The primary function of InsP₃ is to function as a second messenger to release Ca²⁺ from the internal stores. Release from internal stores represents a major source of signal Ca²⁺ for many cells. The major Ca²⁺ store, which is located in the extensive ER network that extends throughout the cell, contains both the ryanodine receptor (RyR) and inositol 1,4,5-trisphosphate receptor (InsP₃R) families (Figure 1). A critical feature of these channels is that they are activated by Ca²⁺. In the case of InsP₃R, therefore, release is triggered by both InsP₃ and Ca²⁺. In effect, InsP₃R functions as a coincident detector, and this property may account for the role of the

InsP₃/Ca²⁺-signaling system in learning and memory. The process of Ca²⁺-induced Ca²⁺ release (CICR) displayed by the RyRs and InsP₃Rs plays a central role in the way many Ca²⁺ signals are generated. This positive feedback mechanism has two important functions in cells. It enables Ca²⁺ entering across the plasma membrane to function as a messenger to release Ca²⁺ from the internal store. This function of CICR was first described in cardiac cells, where the L-type channel Ca²⁺ channel provides an influx of trigger Ca²⁺ that then diffuses into the cell to activate RyR2. The other important function of CICR is to link together these intracellular channels so that the Ca²⁺ being released from one channel diffuses across to neighboring channels that are excited to release further Ca²⁺, thereby setting up regenerative waves. This mechanism is particularly important with regard to the way in which InsP₃ acts to release internal Ca²⁺ (Figure 3).

Spatial and Temporal Aspects of InsP₃/Ca²⁺ Signaling

Those cells that use this InsP₃/Ca²⁺-signaling system usually respond to agonists by generating Ca²⁺ signals with characteristic spatial and temporal patterns (Figure 3). Under resting conditions, the InsP₃Rs are inactive and the Ca²⁺ concentration is held at a steady low level of approximately 0.1 μM.

Figure 2 InsP_3 metabolism. The inositol lipids that function in signaling are embedded in the inner leaflet of the plasma membrane. The precursor lipid is phosphatidylinositol (PtdIns), which is synthesized from inositol and CDP.DAG by a PtdIns synthetase located on the endoplasmic reticulum. PtdIns is transported to the plasma membrane by a PtdIns transfer protein (PITP). The PtdIns in the plasma membrane is successively phosphorylated, first on the 4-position to form PtdIns4P, and then on the 5-position to form PtdIns4,5P₂. Activated cell-surface receptors stimulate phospholipase C (PLC) to hydrolyze PtdIns4,5P₂ to generate inositol 1,4,5-trisphosphate (InsP_3) and diacylglycerol (DAG). InsP_3 activates Ca^{2+} signaling.

Figure 3 The spatial and temporal aspect of InsP_3 -dependent Ca^{2+} signals (see text for further details).

Upon addition of an agonist capable of activating PLC (as described earlier), there is an increase in the formation of InsP_3 that may have two functions. First, the high level of InsP_3 near the membrane may stimulate InsP_3Rs to release Ca^{2+} from stores near the membrane, and this will promote the entry of Ca^{2+} through store-operated channels (SOCs). The InsP_3Rs located deeper within the cell will be progressively sensitized by the InsP_3 that diffuses into the cell and they will begin to release brief Ca^{2+} bursts. Such Ca^{2+} bursts are the elementary events of Ca^{2+} signaling and are the basic building blocks used to create global Ca^{2+} signals. Since these InsP_3Rs are sensitive to both InsP_3 and Ca^{2+} , these initial puffs will be able to recruit neighboring InsP_3Rs to set up a regenerative Ca^{2+} wave that sweeps through the cell and is responsible for the rapid rising phase of a typical Ca^{2+} transient (Figure 3). When Ca^{2+} is released from an individual channel, it feeds back to inhibit further release, and this negative feedback effect limits the amount of Ca^{2+} that is released during each transient. Once the release has switched off, the recovery phase begins and the level of Ca^{2+} returns to resting levels as it either is extruded from the cell or is pumped back into the store. The sequence of events then repeats because the constant influx of Ca^{2+} will load up the store again, and this sets the stage for the next transient, thereby, setting up a regular Ca^{2+} oscillation.

A characteristic feature of most Ca^{2+} signals is that they are presented as a brief Ca^{2+} transient. These transients can either be produced on demand by periodic stimulation as occurs in muscle or neurons, or they can appear as part of a Ca^{2+} oscillation as described in the previous section. InsP_3 acts in many cells to set up Ca^{2+} oscillations through the periodic release of internal Ca^{2+} through the operation of a cytosolic oscillator as described in the previous section (Figure 3). An interesting feature of these oscillations is that their frequency varies with the strength of the external agonist and such frequency modulation represents a mechanism to encode information. Such agonist-dependent cytosolic Ca^{2+} oscillations are a major feature of $\text{InsP}_3/\text{Ca}^{2+}$ signaling in many cell types such as liver cells, mammalian oocytes, vascular and airway smooth muscle cells, astrocytes, and osteocyte precursor cells during their differentiation to osteoclasts.

Inositol 1,4,5-Trisphosphate Receptors

The second messenger InsP_3 functions to mobilize Ca^{2+} from the ER by acting on InsP_3 receptors (InsP_3Rs) (Figures 1 and 3). There are three different InsP_3Rs ($\text{InsP}_3\text{R1}$, $\text{InsP}_3\text{R2}$, and $\text{InsP}_3\text{R3}$), which have fairly similar primary structures and properties. However, they are sufficiently different for cells to express them in varying proportions and in different cellular locations. With regard to their basic function of releasing Ca^{2+} , all behave similarly. Four subunits come together to form functional channels, and the similarity between the three isoforms is reflected in the fact that they can form both homo- and heterotetramers.

The domain structure of one of the subunits reveals that the receptor is organized into three main regions. The transmembrane (TM) and pore (P) domain embeds the receptor in the ER. There are six TM domains, with the pore loop located between TM5 and TM6 (Figure 4). The luminal loops of the pore are glycosylated. There is a very long N-terminal region that has an InsP_3R -binding domain at the end, which is connected to TM1

by the modulatory domain. This modulatory loop has two important functions. First, it has to transmit the conformational change induced by the binding of InsP_3 and Ca^{2+} down to the TM region to open the pore. Second, it is the site where many of the modulators act to alter the release of Ca^{2+} .

As described earlier, the primary regulators of InsP_3R are InsP_3 and Ca^{2+} . The way in which these two messengers cooperate with each other is complicated, but the basic mechanism is that InsP_3 binds to the InsP_3 -binding domain to induce a conformational change, which sensitizes a Ca^{2+} -binding site, and it is the subsequent binding of Ca^{2+} that then acts to open the channel (Figure 4). The effect of Ca^{2+} on the InsP_3R is bimodal; it is stimulatory at low levels of Ca^{2+} , but then becomes inhibitory at concentrations above approximately 300 nM. This dual control of InsP_3R by both InsP_3 and Ca^{2+} is central to its multiple functions in cell signaling. It is central to the mechanism of Ca^{2+} oscillations described earlier (Figure 3). The fact that the opening of InsP_3R depends upon the presence of both InsP_3R and Ca^{2+} has suggested a possible role as a neuronal coincident detector in neurons during learning and memory.

In addition to InsP_3 and Ca^{2+} , there are a large number of other physiological and pharmacological regulators that are able to modulate the activity of the InsP_3Rs .

InsP_3R Agonists

The fungal product adenophostin is 100-fold more active than InsP_3 . It activates the receptor by binding to the InsP_3 -binding site. The InsP_3R is also sensitive to reactive oxygen species (ROS), such as hydrogen peroxide (H_2O_2), which may act by oxidizing the two highly conserved cysteine residues located in the C-terminal region of the molecule. Similarly, the oxidizing agent thimerosal can also activate InsP_3R . When added to intact cells, thimerosal can reproduce Ca^{2+} signals produced by normal stimuli, such as fertilization of mouse oocytes. Adenosine triphosphate (ATP) binds to a site in the modulatory domain where it potentiates the effect of InsP_3 . This stimulatory effect of ATP could provide a mechanism for shaping Ca^{2+} signals to the metabolic state of the cell.

InsP_3R Antagonists

Xestospingins are potent membrane-permeant blockers of InsP_3Rs . However, they can also inhibit the ER Ca^{2+} pump and this may explain some of their inhibitory actions on InsP_3 -induced Ca^{2+} release. Caffeine is an effective reversible inhibitor of InsP_3 -induced Ca^{2+} release. Caffeine may act by competing with ATP, which is an essential co-activator of InsP_3R . The inhibitory effect can be overcome by increasing the concentration of InsP_3 . 2-Aminoethoxydiphenyl borate (APB) is a membrane-permeant inhibitor of the InsP_3R that has proved to be an effective tool for inhibiting Ca^{2+} release.

InsP_3R Modulation

The activity of InsP_3Rs is modulated by protein phosphorylation driven by a number of signaling pathways. The effects of phosphorylation are complex because it can result in either an increase or a decrease in InsP_3 -induced Ca^{2+} release. In the parotid gland, acetylcholine-evoked secretion is potentiated

Figure 4 Activation of the inositol 1,4,5-trisphosphate receptor (InsP₃R) by the cooperative action of InsP₃ and Ca²⁺. Two of the channel subunits (colored red and blue) that make up the tetramer are shown with their pore regions coming together to form the channel. In the resting state (shown on the left), the pore may be held in a closed state by the N-terminal region of one receptor interacting with the C-terminal region of a neighboring receptor. Upon binding first InsP₃ and then Ca²⁺, there is a marked conformational change that removes this N-terminal/C-terminal interaction, and the gate region opens to allow Ca²⁺ to flow out of the endoplasmic reticulum (ER) into the cytoplasm.

by agents that elevate cAMP, which acts by enhancing the degree of Ca²⁺ signaling by phosphorylating InsP₃R. Similar effects occur in liver cells, where both cAMP and cyclic guanosine monophosphate (cGMP) enhance the phosphorylation of the InsP₃R1 and increase the release of Ca²⁺. However, there are other cell types where phosphorylation of the receptor results in a decrease in release. For example, phosphorylation of InsP₃R in vascular smooth muscle cells by cGMP-dependent kinase (cGK) causes a rapid inhibition of Ca²⁺ mobilization. This action of cGMP plays a role in smooth muscle relaxation in response to nitric oxide (NO). This action of cGMP is mediated by an InsP₃R-associated cGMP kinase substrate (IRAG), which is phosphorylated by cGK in smooth muscle cells and is an essential component for the regulation of InsP₃-induced Ca²⁺ release.

Phosphorylation of InsP₃R by protein kinase B (PKB) functions to inhibit InsP₃-induced Ca²⁺ release and this could provide a possible mechanism for the inhibition of Ca²⁺-dependent glycogenolysis by insulin in liver cells.

One of the anti-apoptotic actions of Bcl-2 may depend on the reduction of Ca²⁺ release by InsP₃R.

The Role of the InsP₃/Ca²⁺ Signaling Pathways in Cellular Control Mechanisms

A remarkable feature of the InsP₃/Ca²⁺ signaling pathway is that it participates in the control of a large number of cellular processes (Figure 5). In some cases, it plays a direct role in generating Ca²⁺ signals, whereas, in other cases, it functions

to modulate the Ca²⁺ signals produced by other signaling pathways. The following examples will illustrate the versatility of this Ca²⁺ signaling mechanism. As described earlier, the InsP₃-dependent Ca²⁺ signal appears as regular oscillations as occur during fertilization, the control of metabolism in liver cells, contraction in smooth muscle cells, and the function of the interstitial cells of Cajal. In mammalian oocytes, there is an unusual activation mechanism that depends upon the sperm fusing with the oocyte to introduce the sperm-specific phospholipase C ζ (PLC ζ), which then begins to hydrolyze PtdIns4,5P₂ to generate InsP₃ that initiates Ca²⁺ oscillations (Figure 1). These oscillations then control various oocyte responses, such as cortical granule release, the block to polyspermy, the completion of meiosis, and the initiation of the cell-cycle program leading to embryonic development.

Cell Proliferation

The InsP₃/Ca²⁺ signaling pathway also has a role to play in the control of cell proliferation in many cell types. This role is well established in lymphocyte activation, which is initiated by antigen binding to the T-cell receptor (TCR) that then recruits PLC γ 1 to produce InsP₃ that acts through InsP₃R to release Ca²⁺ from the internal store. As the ER empties, it sends a signal to the Ca²⁺ release-activated Ca²⁺ (CRAC) channel responsible for maintaining Ca²⁺ entry for the 2-h period required to induce lymphocytes to grow. The coupling between store emptying and activation of the CRAC channel depends

Figure 5 Diverse functions of the $\text{InsP}_3/\text{Ca}^{2+}$ signaling pathway. The mobilization of Ca^{2+} by inositol 1,4,5-trisphosphate (InsP_3) functions in the control of many different cellular processes in a wide range of cell types. Details of some of these functions are outlined in the text.

on an interaction with the stromal interaction molecule 1 (STIM1) located in the ER. Both the release and entry processes generate the Ca^{2+} signal to stimulate calcineurin (CaN) to dephosphorylate the nuclear factor of activated T cells (NFAT), which enters the nucleus where it initiates the transcriptional events that lead to cell proliferation.

Neuronal Ca^{2+} Signaling

The brain is particularly rich in the components that function in the $\text{InsP}_3/\text{Ca}^{2+}$ signaling pathway, which may play an important role in contributing to various neuronal processes, such as the changes in synaptic plasticity that underlie learning and memory. In the case of Purkinje neurons, InsP_3R are located on the ER that extends into the multitude of spines that decorate the dendritic tree. The metabotropic receptors, which are also located on the spines, are responsible for generating InsP_3 that contributes to the process of long-term depression (LTD) that is responsible for motor learning. Dysregulation of the $\text{InsP}_3/\text{Ca}^{2+}$ signaling system has been implicated in Alzheimer's disease (AD).

Cardiac Cells

Cardiac cells provide another example of how the $\text{InsP}_3/\text{Ca}^{2+}$ signaling pathway can modify the ongoing Ca^{2+} signaling system that drives contraction. In both atrial and ventricular cells, microdomains of Ca^{2+} known as ' Ca^{2+} sparks' create the global signal that drives contraction. This basic signaling system can be modified by the $\text{InsP}_3/\text{Ca}^{2+}$ signaling system in both atrial and ventricular cells. Under normal conditions, the

atrial sparks are confined to a region near the plasma membrane because they fail to breach a mitochondrial firewall. Stronger contractions are induced following stimulation of the atrial cells by endothelin, and this large positive inotropic response depends on the ability of InsP_3 to enhance the cell-surface sparks so that they breach the mitochondrial firewall to stimulate the nonjunctional RyR2s to ignite the Ca^{2+} wave that produces the larger global signals. Excessive activation of the $\text{InsP}_3/\text{Ca}^{2+}$ signaling pathway might be the cause of atrial arrhythmias.

In the case of ventricular cells, the $\text{InsP}_3/\text{Ca}^{2+}$ signaling pathway may also contribute to positive inotropic responses to agonists, such as endothelin, by enhancing the sparks that are responsible for excitation-contraction coupling. The spatial organization of the enhanced Ca^{2+} signal responsible for this positive inotropic response may be particularly important for understanding the processes responsible for cardiac hypertrophy and heart disease. During normal transients, each Ca^{2+} spark is located primarily in the cytoplasm where it functions to drive contraction. However, in the presence of agonists such as endothelin that increase the level of InsP_3 , this cytosolic signal may be amplified by the release of Ca^{2+} by InsP_3Rs located near the nucleus to give a nuclear-cytosolic signal capable of stimulating the transcriptional events responsible for hypertrophy.

Glossary

Gonotrophic cycle Reproductive process of ovarian development and egg laying in blood-feeding insects.

Hemolymph The circulatory fluid of insects, similar to blood or lymphatic fluid in other organisms.

Holometabolous insects Insects that undergo complete metamorphosis from eggs to larvae to pupae to adults.

Overview of Insects

Insects are the most abundant multicellular organisms on planet Earth and are thought to account for >70% of all species. So far, over 1 million insect species have been identified, with estimates putting the total number of insect species worldwide at 6–10 million. Insects are invertebrates that represent a class of arthropods characterized by three pairs of jointed legs; a three-part body consisting of a head, thorax, and abdomen; compound eyes; a chitin exoskeleton; and two antennae. Holometabolous insects hatch from eggs and progress through three distinct life stages. Newly hatched eggs produce larvae that go through metamorphosis, which is separated by molts. Since the chitin exoskeleton cannot accommodate the growing insect, molting provides a way for insects to shed their exoskeleton multiple times until they reach the pupal stage in which they complete metamorphosis in a protected shell called a pupal case. In the final developmental stage, the adult insect emerges from the pupal case, and within a few hours or days, females and males mate to produce fertilized eggs. In some other insects (hemimetabolous), the adult form from the hatching can be reached gradually with successive molts during a process called incomplete metamorphosis (cockroaches and grasshoppers). In this type of development, the immature stages (nymphs, or when aquatic, naiads) are like the adults except in size, flight, and sexual maturity.

Endocrine regulation in insects relies on a large number of peptide and nonpeptide hormones, several of which have been studied in great detail. Three of the best-characterized insect hormones are ecdysone, juvenile hormone (JH), and prothoracicotropic hormone (PTTH), all of which play important roles in insect metamorphosis and reproduction. Ecdysone, and most likely JH, bind to receptor proteins that function as transcription factors, which directly or indirectly regulate the expression of specific target genes. In contrast, PTTH binds to a membrane-bound receptor tyrosine kinase in the prothoracic gland of immature insects and initiates an intracellular phosphorylation cascade that activates ecdysone synthesis. Ecdysone synthesis in adult insects occurs primarily in the ovaries in response to the brain neuropeptide ovarian ecdysteroidogenic hormone.

Insect Biochemistry

Insect Metabolomics

Insects provide an ideal model system to investigate metabolic regulation in multicellular organisms because they can often

be easily manipulated for biochemical studies, and for some of the most important insect species, whole genome sequence information is readily available, which greatly facilitates molecular genetic approaches. Metabolomics is the systematic study of small molecules that are utilized or generated by metabolic processes in living cells. The most common type of metabolomic study involves collecting biochemical samples from cell or tissue cultures, or whole organisms, under various conditions that can be quantitatively and qualitatively analyzed by high-performance liquid chromatography (HPLC) and mass spectrometry. Based on bioinformatic analysis of genome sequences, it is often possible to predict what metabolic pathways in insects are responsible for changes in metabolite profiles as a consequence of environmental signals or genomic variations in metabolic enzymes.

One example of how insect biochemistry can be investigated using a metabolomics approach is the mass spectrometry-based study of the *rosy* (*ry*) mutation in *Drosophila melanogaster*. The *ry* mutation maps to the xanthine oxidase gene that encodes an enzyme required to convert xanthine, a product of purine degradation, to uric acid. In *D. melanogaster*, loss of xanthine oxidase causes a reddish brown eye color due to a deficiency in red pigment, which is how this mutation was first identified. In humans, xanthine oxidase deficiency leads to a condition called xanthinuria that is characterized by xanthine accumulation in the urinary tract and kidney. Using whole-body extracts of *D. melanogaster* wild-type and *ry* mutant flies, mass spectrometric analysis revealed significant increases in xanthine and hypoxanthine, as well as higher levels of guanine metabolites and bipterins. Surprisingly, the *ry* mutant defect in xanthine oxidase was associated with a 15-fold increase in glycerophosphocholine levels, presumably due to osmotic stress caused by the inability to excrete uric acid.

Another example of how metabolomics have been used to investigate biochemical processes in insects, was a recent study in which larvae of the Antarctic midge *Belgica antarctica* were exposed to high heat, freezing temperatures, or desiccation, and the levels of 75 metabolites were analyzed by mass spectrometry. It was found that the steady-state level of a variety of sugars, amino acids, and citric acid cycle intermediates were differentially affected by these extreme environmental conditions. Specifically, levels of alanine, aspartate, mannitol, and urea were elevated after 6 h of freezing conditions (−10 °C), whereas glycine and serine levels were decreased. Similarly, it was found that levels of α -ketoglutarate and putrescine were elevated after 1 h at 30 °C, but glycerol, serine, and glucose

levels were decreased after a 1 h heat shock. Since serine levels decreased under both conditions of extreme cold and heat, as well as when the larvae were subjected to desiccating conditions, it was proposed that decreased serine levels may be a marker of environmental stress in this insect species.

Blood Meal Metabolism in Mosquitoes

Because of their role as biological vectors for many of the arthropod-borne infectious diseases in humans, mosquitoes have been extensively studied at the biochemical level. Mosquitoes are responsible for transmitting not only malarial parasites and a variety of arboviruses, but also nematode worms that cause lymphatic filariasis. It is estimated that 40% of the world's population is at risk of being infected by malaria, with 300 million people being infected each year and over 1 million deaths. Malaria is primarily transmitted by the mosquito species *Anopheles gambiae* in Africa, *Anopheles albimanus* in South America, and by *Anopheles stephensi* in Asia. The other major mosquito-borne disease affecting humans is Dengue fever, which can develop into Dengue hemorrhagic fever and be fatal. *Aedes aegypti* mosquitoes transmit Dengue virus and are one of the most rapidly spreading human disease vectors in the world. It is estimated that up to 3 billion people in the Americas, Africa, and Asia are at risk of being infected by Dengue virus, and that of the nearly 50 million new Dengue infections each year, 20 000 deaths will occur from Dengue hemorrhagic fever.

Newly emerged *Ae. aegypti* female mosquitoes feed on nectar for several days until they are able to take their first blood meal (males do not blood feed). The blood meal is required for *Ae. aegypti* egg development and results in the deposition of ~100 fertilized eggs within 72 h of feeding. This process of blood digestion, oocyte maturation in the ovaries, and the laying of fertilized eggs is called the gonotrophic cycle. In the course of each gonotrophic cycle, blood meal metabolism requires efficient retrieval of nutrients, and rapid excretion of toxic products such as ammonia (defined here as NH_3 , NH_4^+ , or combination of both), in order to produce viable eggs. This is an amazing accomplishment considering the mosquito's size. A typical female mosquito weighs ~2 mg and can consume a blood meal of ~2 μl in few minutes. Taking into account the mass of water (~1.6 mg), protein (~400 μg), lipid (~10 μg), and carbohydrate (~1 μg) in this 2- μl blood meal, it can be

calculated that the female mosquito consumes her own body weight in a single feeding. This feat would be equivalent to a 125 lb woman drinking a 12 gallon smoothie that contains 25 lbs of hamburger meat, 0.5 lb of butter, and 2 tbs of sugar. As metabolically challenging as blood meal digestion must be, the female *Ae. aegypti* mosquito is highly capable and typically completes 4–7 gonotrophic cycles to produce up to 400 mosquito progeny over a 1-month period.

The vast majority of nutrients, in a typical mosquito blood meal, are derived from blood meal proteins, of which three constitute 80% of the total protein. These are hemoglobin (~330 μg), serum albumin (~50 μg), and IgG antibodies (~15 μg). Biochemical and molecular genetic studies have shown that mosquito blood meal digestion is initiated by endoprotease and exopeptidase enzymes that are secreted into the lumen by midgut epithelial cells within 30 min of feeding. Although mosquitoes require 10 of the 20 naturally occurring amino acids in their diet (essential amino acids), metabolic labeling studies using ^{14}C -protein revealed that only ~14% of the ingested protein is recycled into newly synthesized maternal proteins or egg proteins (Figure 1). In contrast, ~70% of the amino acids retrieved from the blood meal are deaminated to generate reduced carbon that is used for immediate energy needs or excreted as waste. Blood meal-derived amino acids are also used for lipogenesis to supply stored energy for the female mosquito (~10%), and converted to egg lipids that are used to complete oocyte maturation (~6%).

Urea Synthesis in *Ae. aegypti*

Excess nitrogen cannot be stored in cells, and therefore, nitrogen balance must be highly regulated to prevent ammonia toxicity, while at the same time, providing sufficient nitrogen for the biosynthesis of amino acids, nucleotide bases, and coenzymes. Aquatic organisms excrete most of their excess nitrogen directly into water as ammonia, whereas animals that spend all or part of their life cycle on land excrete nitrogen as uric acid or urea. Mammals synthesize urea via a metabolic pathway called the urea cycle that derives the two nitrogen atoms in urea from carbamoyl phosphate and aspartate. Certain amphibians and some fish do not express urea cycle enzymes; however, the urea they produce is the result of uric acid degradation by the uricolytic pathway (Figure 2). The

Figure 1 Blood meal metabolism in female *Aedes aegypti* mosquitoes. The major nutrient in the mosquito blood meal is protein, which is converted to amino acids that are then deaminated and used as reduced carbon for energy conversion and lipid synthesis, or used directly for the synthesis maternal and egg proteins.

Figure 2 The uricolytic pathway converts uric acid into urea. Feeding experiments in *Aedes aegypti* mosquitoes with ¹⁵NH₄Cl have been used to quantitate uricolytic pathway intermediates by mass spectrometry (bolded N atoms were ¹⁵N-labeled in these experiments). RNAi-mediated knockdown of urate oxidase expression in blood-fed mosquitoes confirmed that the uricolytic pathway is functional under normal physiological conditions.

uricolytic pathway converts uric acid to urea and glyoxylic acid through a three-step process requiring the enzymes urate oxidase, allantoinase, and allantoicase.

Early metabolic studies of nitrogen metabolism in blood-fed *Ae. aegypti* mosquitoes showed that excess nitrogen produced by blood meal digestion is excreted as ammonia, amino acids, uric acid, and urea. Based on studies in vertebrates, it was assumed that the urea present in mosquito feces was produced by converting excess dietary arginine into urea via the arginase reaction. However, by using a combination of ¹⁵N-isotope labeling experiments, bioinformatic analysis of the *Ae. aegypti* genome sequence, and RNAi-mediated knockdown of urate oxidase expression, it was recently shown that a portion of this excreted urea is in fact derived from the uricolytic pathway. As illustrated in **Figure 2**, mass spectrometric analysis of uric acid containing ¹⁵N-labeled in two positions revealed that uric acid is metabolized to 2 mol of ¹⁵N-labeled urea, thereby providing biochemical evidence that the uricolytic pathway is functional in *Ae. aegypti* mosquitoes. In addition, RNAi-mediated knockdown of urate oxidase expression in ¹⁵NH₄Cl-fed mosquitoes was found to significantly decrease the amount of ¹⁵N-urea in the feces. Similarly, knocking down urate oxidase expression in blood-fed mosquitoes resulted in a buildup of uric acid in mosquito tissues. Given the unusually high-protein content of the mosquito blood meal, it is likely that the uricolytic pathway provides a mechanism for the adult female mosquito to maximize nutrient uptake while minimizing the risk of ammonia toxicity.

Insect Hormones

Endocrine regulation in insects is complex with many different types of hormones involved, including steroids (ecdysone), lipid compounds (JH), multiple peptide hormones (PTTH; ovarian ecdysteroidogenic hormone, OEH; adipokinetic hormone, AKH), and biogenic amines (serotonin, DOPA). The discussion here focuses on the two major gonadotropins, ecdysone and JH, and the peptide hormone PTTH, which

regulates ecdysteroidogenesis in the larval and pupal prothoracic gland. Insect endocrinology has been extensively studied in *D. melanogaster*, *Manduca sexta*, and *Ae. aegypti*, primarily with regard to the structure and function of 20-hydroxyecdysone (20E), the biologically active form of ecdysone, JH-III, the most abundant JH found in insects, and a variety of peptide hormones, of which PTTH is one of the best characterized at the biochemical level.

20-Hydroxyecdysone

The steroid hormone ecdysone is major regulator of molting, metamorphosis, and reproduction in insects. The site of ecdysone synthesis in insect nymphs or larvae is the prothoracic gland in response to PTTH signaling, whereas in the adult the majority of ecdysone is synthesized in the follicle cells of the ovaries. Ecdysone is secreted into the hemolymph and absorbed by fat body cells where it is converted to 20E by the enzyme ecdysone 20 monooxygenase, a P450 enzyme expressed in fat body tissue. The 20E product of this reaction is released into the hemolymph where it travels to target tissues by classic endocrine mechanisms. Physiological studies of 20E function in insects have shown that it controls the molting process during metamorphosis, as well as a number of other physiological processes including the wandering behavior of larvae, development of complex neuronal networks, and oocyte maturation in adult female insects.

In adult female mosquitoes, 20E is required for completion of the gonotrophic cycle and production of viable eggs. Shortly after taking a blood meal, the neuropeptide OEH is released from the brain and is transported by the hemolymph to the ovaries where it stimulates the synthesis of ecdysone and 20E via a cyclic-AMP second-messenger signaling cascade. The biochemical response to 20E production is yolk protein synthesis in the fat body, and egg maturation in the ovaries, a process known as vitellogenesis (the various yolk proteins are named vitellogenins). The yolk proteins are secreted by fat body cells into the hemolymph where they are recovered by receptor-mediated endocytosis in the developing oocytes. Within 48h

(b) 20E binds to a hydrophobic pocket in the ligand-binding domain of the ecdysone receptor protein. Molecular structure based on PDB file 2R40. (c) Chemical structure of the terpenoid-derived hormone JH-III.

of blood feeding, 20E concentrations in the hemolymph decrease to previtellogenic levels, and JH titers rise sharply in preparation for the next blood meal and gonotrophic cycle.

The chemical structure of 20E is shown in **Figure 3(a)** where it can be seen that it consists primarily of a central four-ring core derived from cholesterol, as is true of all steroidal hormones that have been characterized biochemically. Insects cannot synthesize cholesterol *de novo*, and therefore, ecdysone biosynthesis is dependent on dietary cholesterol uptake during the larval and adult stages. The mechanism of action of 20E is mediated through binding and activation of a heterodimeric transcription factor consisting of two DNA-binding nuclear receptor proteins called the ecdysone receptor (ECR) and ultraspiracle (USP). The ligand-binding domain of the ECR protein from *Heliothis virescens* (Tobacco budworm) contains numerous hydrophobic amino acids, such as phenylalanine, tyrosine, and tryptophan, that line the 20E-binding pocket (**Figure 3(b)**).

Studies of the *D. melanogaster* ECR protein have shown that dimerization with USP occurs in the absence of 20E, but upon 20E binding, the ECR–USP complex is translocated to the nucleus where it interacts with specific DNA sequences that function as ecdysone response elements. The molecular structure of the DNA-binding domains of the *D. melanogaster* ECR and USP proteins bound to a pseudopalindromic ecdysone response element located upstream of the hsp27 gene promoter is shown in **Figure 4**. It can be seen that the USP-subunit binds within the major groove of DNA to the 5' half-site of the hsp27 response element and makes contacts through an α -helical region of the protein with nucleotides on both DNA strands. Similarly, the ECR subunit binds to the 3' half-site sequence that also lies within the major groove of the DNA helix and makes several direct nucleotide contacts. The net result of this sequence-specific DNA-binding event is the recruitment of auxiliary transcription factors that bind to either adjacent DNA sequences, or through protein–protein interactions, to the ECR–USP complex. One of the most thoroughly characterized examples of 20E-mediated regulation of gene expression in insects is the induced expression of multiple vitellogenin genes in the fat body of blood-fed female *Ae. aegypti* mosquitoes. Using quantitative real-time polymerase chain reaction assays, it was shown that 20E signaling through

Figure 4 20E signaling is mediated by a nuclear receptor heterodimer consisting of the ecdysone receptor (ECR) and the ultraspiracle (USP) proteins. The DNA-binding domains of ECR and USP make direct contacts to nucleotide bases contained in the two half-site sequences of the ecdysone response element in the *Drosophila melanogaster* hsp27 gene (bolded nucleotides). Molecular structure based on PDB file 2HAN.

the ECR–USP heterodimeric complex induces *Ae. aegypti* vitellogenin gene expression by as much as 10000-fold within 24 h of blood feeding.

Juvenile Hormone (JH-III)

Insects have a class of terpenoid compounds, collectively called JHs that regulate metamorphosis. The best-characterized and most abundant of these hormones is JH-III, the structure of which is shown in **Figure 3(c)**. JHs were first discovered in the kissing bug *Rhodnius prolixus* in 1934 by Vincent Wigglesworth who described them as compounds that inhibit the final stage of metamorphosis when applied to the insect exoskeleton. He also showed that JH was required in adult insects to promote egg maturation. JH-III is synthesized in a pair of glands in the insect head called the corpora allata and functions in much the same way as 20E in that it regulates gene expression through a receptor-mediated signaling process. In fact, both 20E and JH-III have been found to regulate the same developmental process, but often in an opposing way, with JH-III antagonizing, or modulating, 20E signaling functions. Peak levels of JH-III and 20E in the hemolymph of female mosquitoes are diametrically opposed depending on whether the mosquito is sugar fed or blood fed, respectively.

Although much is known about the synthesis and biological function of JH-III in several insect species, it is still not exactly clear how JH-III regulates gene expression in target tissues. The search for a JH receptor in *D. melanogaster* has so far led to two candidate proteins, both of which are DNA-binding transcription factors. One is the USP protein that forms a complex with ECR and has been found to bind JH-III as a ligand with low affinity ($\sim 10^{-7}$ M). More recent studies have reported that USP also binds the metabolic precursor to JH-III, called methyl farnesoate, with high affinity ($\sim 10^{-9}$ M), which is closer to what would be expected for a physiological ligand of a typical nuclear receptor protein.

The second candidate JH receptor is a basic helix-loop-helix protein encoded by the methoprene-tolerant gene (*Met*) that binds JH-III with affinities in the nanomolar range. *Met* contains a PAS domain that is 40% identical to the dioxin receptor translocator protein ARNT which binds to the dioxin receptor, another ligand-activated transcription factor. Based on studies showing modulation of 20E-mediated transcription by increased levels of JH-III, it has been proposed that ECR-USP heterodimers might form complexes with *Met* in a way that facilitates cross-talk modulation of gene expression by E20 and JH-III at specific promoters. In addition, several other DNA-binding proteins in *D. melanogaster*, called Chd64 and FKBP39, have been shown by yeast two-hybrid assays to be interaction partners with *Met* and to bind with high affinity to DNA sequences that function as JH response elements.

Prothoracicotropic Hormone

The neuropeptide PTTH is synthesized in the corpora allata gland in the insect brain and functions in metamorphosis as a hormonal activator of ecdysone synthesis in the prothoracic gland. The existence of PTTH was first described in the 1920s by Stefan Kopec, a Polish biologist, who used decapitation experiments to show that the insect head is required for molting. Later, Vincent Wigglesworth confirmed the presence of a brain hormone distinct from JH that was required for insect metamorphosis. The active form of PTTH is homodimer of identical subunits, each containing a proteolytically processed peptide of 109 amino acids. Because of its similarity to other growth hormones, it was hypothesized that PTTH most likely binds to a growth hormone-like receptor present in prothoracic gland cells during the molting cycle. A bioinformatics approach was recently used to identify receptor tyrosine kinase transcripts that are expressed in the *D. melanogaster* prothoracic gland at times when PTTH activity is known to be required for metamorphosis. One of the candidate genes identified was the Torso receptor tyrosine kinase, which was subsequently shown by genetic and biochemical analyses to be the long sought PTTH receptor. It was found that PTTH binding to the *D. melanogaster* Torso protein on the surface prothoracic gland cells stimulates the Ras → Raf → ERK intracellular signaling pathway and leads to the activation of ecdysone biosynthesis (Figure 5). Although several molecular details of ecdysteroidogenesis in the insect prothoracic gland still need to be resolved, at least six different P450 enzymes have recently been identified as essential components of the pathway in *D. melanogaster*. The genes encoding these P450 enzymes are called the Halloween genes because of their lethal mutant

Figure 5 The insect neuropeptide hormone PTTH induces ecdysone synthesis in prothoracic gland cells by binding to and activating the receptor tyrosine kinase protein Torso. Activation of the Ras → Raf → ERK signaling pathway by Torso leads to stimulation of P450 enzyme activity and initiation of the ecdysteroidogenesis pathway. The Halloween genes discovered in *Drosophila* encode six of these p450 enzymes.

phenotype that is characterized by a defective exoskeleton. The *D. melanogaster* Halloween genes were first described by Eric Wieschaus and Christiane Nusslein-Volhard using a genetic screen for developmental mutants and creatively named *spook*, *spookier*, *phantom*, *disembodied*, *shadow*, and *shade*. The biochemical function and enzymatic properties of these six P450 enzymes are currently being investigated.

Glossary

Beta-cell threshold for glucose-stimulated insulin release

The level of glucose required to initiate insulin release, that is, about 5 mM. This beta-cell threshold is the critical determinant of the glucose setpoint of the body.

Glucokinase (GK) disease Hypo- and hyperglycemia syndromes in humans caused by activating and inactivating mutations of glucokinase. This experiment of nature is the most compelling evidence for the glucokinase glucose sensor concept and its importance in understanding glucose homeostasis.

Glucokinase glucose sensor Glucokinase (also known as hexokinase IV or D) phosphorylates D-glucose using adenosine triphosphate (ATP), forming glucose-6-phosphate. The enzyme serves as a glucose sensor of the pancreatic beta cells because it is rate limiting for glucose metabolism (i.e., glycolysis and oxidation), which is an absolute prerequisite for the triggering of insulin secretion.

Glucose setpoint of the body Blood glucose level maintained precisely by the fine-tuning of opposing processes that either produce or consume glucose. In humans, this setpoint is close to 5 mM.

Alpha and beta cells are the predominant cell types in microscopic endocrine organs called the 'islets of Langerhans', which are scattered throughout the exocrine pancreas and produce, store, and secrete the hormones glucagon and insulin, respectively. Secretion of these hormones is regulated by fuels (glucose, amino acids, and fatty acids) or through neuroendocrine input. Insulin and glucagon in turn regulate the metabolism of these fuels. Loss of beta cells by autoimmune destruction or impairment of their function by poorly understood mechanisms are the causes of type I or type II diabetes mellitus (T1DM or T2DM), respectively. Individuals with T1DM require insulin substitution therapy for survival, and those with T2DM can manage their disease with diet restrictions, exercise, and a variety of drugs with different mechanisms of action. It is thus of critical importance to develop a comprehensive understanding of insulin- and glucagon-producing cells of the pancreas.

Introduction

Pancreatic alpha and beta cells play the predominant role in maintaining glucose homeostasis in humans and many laboratory animals and keep the blood glucose in the narrow range of 5–8 mM in response to the demands of feeding and fasting. Both cells have a threshold of approximately 5 mM glucose for stimulation of hormone release. The alpha cell is triggered to release glucagon when the glucose falls below this level, whereas the beta cell is activated to secrete insulin when this level is exceeded. Expressed differently, the inhibitory glucose dependency curve for alpha cells and the stimulatory glucose dependency curve for beta cells have their crossover point at 5 mM, which is the setpoint of the system for glucose homeostasis. (Note that alpha-cell deinhibition with falling glucose manifests itself most clearly when these cells are also under the influence of physiological stimuli, e.g., amino acids, a condition that is met *in situ*.) Auxiliary

neuroendocrine mechanisms involving acetylcholine, catecholamines, glucagon-like peptide 1 (GLP-1), and gastric inhibitory peptide (GIP) enhance or blunt the response of the pancreatic endocrine cells to fuel stimulation. The other two fuel classes, amino acids (AAs) and fatty acids (FAs), stimulate insulin release in a strictly glucose-dependent manner. AAs are the most effective fuel stimulant of alpha cells at biologically relevant concentrations (e.g., 3.5–7.0 mM of the physiological mixture of 20 AA enhances glucagon release markedly when glucose falls below 5.0 mM).

This article focuses on the mechanisms of glucose-stimulated insulin release (GSIR) because this issue is central to beta-cell function and because knowledge of this aspect of beta-cell biology and glucose homeostasis is well established, much less tenuous or controversial than current understanding of how the other fuels act on alpha and beta cells. However, when important and possible, how glucose and other fuels or neuroendocrine factors interact with these two types of pancreatic endocrine cells is discussed.

The Beta-Cell Glucokinase Glucose Sensor and the Threshold for GSIR

The glucokinase glucose sensor concept and the threshold concept for GSIR explain a great deal about beta cells and the nature of glucose homeostasis in humans and most laboratory animals. Glucokinase (GK) serves as the beta cell's cytosolic glucose-sensing device and contributes a critical element to the regulatory feedback loop or signaling chain that interconnects blood glucose, the beta cell, the hormone insulin, and the major insulin target tissues (i.e., the liver, muscle, and adipose tissue). The kinetic characteristics of GK are ideally suited for this purpose: the k_{cat} for glucose phosphorylation is about 60 s^{-1} ; the glucose $S_{0.5}$ (i.e., the glucose concentration resulting in half-maximal enzymatic activity) is about 8.0 mM; the glucose dependency curve of GK action is sigmoidal as

indicated by a Hill coefficient (n_h) of 1.7; the adenosine triphosphate (ATP) K_m is about 0.4 mM, indicating that the enzyme operates *in vivo* near saturation with its second substrate; finally, there is no feedback inhibition by glucose-6-P in contrast to the highly effective inhibition of other hexokinases by this metabolite. Of great theoretical interest and practical importance is the recent recognition of an allosteric activator site on GK that explains the mechanism of action and efficacy of a newly discovered class of antidiabetic agents (GK activators (GKAs); see following discussion). Beta-cell GK is inducible by glucose (maximally five- to tenfold compared to basal levels at 1.0 mM glucose) through mechanisms yet to be fully clarified. Note that hepatic GK is induced by insulin in a glucose-independent manner and is also activated by GK activators (GKAs). Note also that hepatic GK is regulated by the inhibitory GK regulatory protein (GKRP), which sequesters the enzyme to the nuclear compartment from which GK is released by glucose during hyperglycemia. By contrast, GKRP seems to be of little importance for beta-cell GK function. Differential expression control of islet and hepatic GK is explained by the presence of two tissue-specific promoters in one single gene. Due to these characteristic features, GK determines the rate of beta-cell glycolysis with a control strength approaching unity, outperforming all other metabolic steps. Glycolytic flux of beta cells is therefore a function of substrate pressure rather than of

energy demand, which determines glucose use of many other tissues, including brain and muscle.

These features are a prerequisite for the glucose sensor role of GK; they do not, however, explain the 5-mM setpoint for glucose homeostasis and threshold for GSIR. This threshold is a function of the biophysical characteristics of the K^+ and Ca^{2+} channels of the beta-cell membrane (Figure 1). The K -ATP channel is a hetero-octamer composed of four subunits each of the Kir6.2 inward rectifier and the drug target SUR-1 and is regulated by the phosphate potential of the beta cells. Important for physiology, it is inhibited by ATP^{4-} and activated by $MgADP^{2-}$ such that a decrease of the cytosolic ATP/ADP ratio determines K^+ conductivity and consequently the membrane potential. Enhanced glucose metabolism increases this ratio and depolarizes the beta cell. Alterations of the membrane potential are transmitted to the voltage-sensitive L-type Ca^{2+} channel. Depolarization stimulates Ca^{2+} influx and leads to elevation of the free intracellular calcium ($[Ca^{2+}]_i$). The combination of high ATP and $[Ca^{2+}]_i$ elicits insulin release. Important for understanding the threshold phenomenon for GSIR is the fact that the decrease of the K^+ conductivity is a graded function of glucose metabolism (i.e., the GK rate), whereas the L-type Ca^{2+} channel has a well-defined triggering potential of -60 to 50 mV, which happens to be reached when GK or glycolysis operates at 25–30% of

Figure 1 Signaling pathways in pancreatic beta cells. Six distinct signaling pathways in pancreatic beta cells are depicted (1–6). Abbreviations are as follows, with a–g identifying initial or other critical steps for these pathways: GK, glucokinase (a); the K_{ATP} channel complex, consisting of ATP-sensitive K^+ channels and sulfonyl urea receptor type 1 (SUR-1) subunits (b); VDCC, voltage-dependent Ca^{2+} channel or L-channels (c); acetylcholine (ACh) and muscarinic receptor type 3 (m3) (d); SOCC, store-operated calcium channels (e); GLP-1, glucagon-like peptide-1 and receptor (f); IBMX, 3-isobutyl-1-methylxanthine, a phosphodiesterase inhibitor (g). Other abbreviations are as follows: AC, adenylate cyclase; cAMP, cyclic AMP; PKC, protein kinase C; PKA, protein kinase A; DAG, diacylglyceride; IP3, inositol triphosphate; GEFII, cAMP-guanidine nucleotide exchange factor (or Epac2); $\Delta\Psi$, change of cell membrane potential. Additional abbreviations are explained in the text. Modified from Doliba NM, Qin W, Vatamaniuk MZ, et al. (2004) Restitution of defective glucose-stimulated insulin release of sulfonylurea type 1 receptor knockout mice by acetylcholine. *American Journal of Physiology – Endocrinology and Metabolism* 286(5): E834–E843.

its normal capacity, that is, at 5.0 mM glucose. Note that extra- and intracellular glucose are virtually identical at all times as a result of high-capacity glucose transport by Glut-2. This basic signaling pathway from glucose to insulin release as previously outlined is termed the 'triggering pathway (TPW)'. It is complemented by the so-called augmentation pathway (APW), which potentiates glucose action, but the molecular basis of the latter remains to be defined in detail.

Model Experiments to Illustrate the Operation of the TPW and the APW

The APW comes into play when $[Ca^{2+}]_i$ and ATP/ADP are elevated by the TPW and when the beta cells are activated in addition by acetylcholine, GLP-1, or GIP. Model experiments with perfused islets isolated from control mice and from mice lacking functional K^+ channels (i.e., from SUR-1^{-/-} knockout (KO) mice) illustrate many of the points discussed in the preceding section (Figure 2). First, beta cells from SUR-1^{-/-} do not show GSIR when acetylcholine is absent because the TPW is blocked in contrast to controls. Second, the distinctly different secretion profiles for GSIR evoked in control and SUR-1^{-/-} islets in the presence of low acetylcholine illustrate that the glucose response caused by the combined TPW and

APW in the control has a clear threshold and is blocked by diazoxide (a potassium channel opener (KCO)) as expected, whereas that of the APW alone as seen in the SUR-1^{-/-} islets is clearly graded (lacking a threshold) and is not blocked by diazoxide, again as expected. Both signaling pathways operate during a meal and result in the robust, threshold-based GSIR as mimicked by the experiment shown in Figure 2 for control islets.

AAs and FAs as Glucose-Dependent Stimuli of Beta Cells

Stimulation of insulin release by a physiological mixture of 20 AAs (20-AASIR) is biologically highly relevant but less well understood than GSIR. It is established, though, that 20-AASIR of normal islets has an absolute glucose requirement, that is, at least 2.5 mM. It is not clear which signaling pathways are involved, but it is likely that the TPW as sketched in the preceding discussion plays a role. Assuming a major role for metabolism in 20-AASIR, it must be postulated that transport into the cell and subsequent transamination are efficient processes. AA metabolism requires transamination as the first step, generating glutamate and alanine as the major products, followed by oxidative deamination of glutamate with

Figure 2 Experimental dissection of signaling pathways in glucose-stimulated insulin release (GSIR). Acetylcholine increases the insulin release in SUR-1^{-/-} islets in the absence of glucose, demonstrating marked hypersensitivity to the transmitter compared to controls. Acetylcholine also reconstitutes defective GSIR by these islets. After stable insulin secretion rates were achieved at 30 min, islets were perfused in the absence of glucose for 60 min (t-30–t-90). Following addition of neostigmine (a cholinesterase inhibitor) and acetylcholine, a glucose ramp (from 0 to 30 mM with an 0.8 mM increment per min) was applied for 37.5 min to control and SUR-1^{-/-} islets, and glucose was then maintained constant at 30 mM for about 30 min longer in the continued presence of acetylcholine (t-90–t-160). The experiment was completed by perfusing islets with Krebs–Ringer bicarbonate (KRB) solution lacking glucose and drugs. The rise in the glucose concentration in the perfusate led to an increase in hormone secretion in SUR-1^{-/-} islets as well as in the controls. However, note the different patterns of the release profiles. Also, appreciate that in the absence of acetylcholine and neostigmine, SUR-1^{-/-} islets did not respond to glucose in contrast to the controls (not shown). Diazoxide, a K_{ATP} channel activator, immediately decreased insulin release to baseline in control but was unable to block hormone release in SUR-1^{-/-} islets. Reproduced from Doliba NM, Qin W, Vatamaniuk MZ, et al. (2004) Restitution of defective glucose-stimulated insulin release of sulfonylurea type 1 receptor knockout mice by acetylcholine. *American Journal of Physiology – Endocrinology and Metabolism* 286(5): E834–E843.

glutamate dehydrogenase (GDH) to form nicotinamide adenine dinucleotide phosphate-oxidase (NAD(P)H), which is converted to ATP. The need for the α -ketoacids, α -ketoglutarate, and pyruvate as acceptors for the transamination reaction may explain, at least in part, the absolute requirement for glucose. It is also possible that AA metabolism generates metabolic coupling factors in addition to energy, with glutamate and glutamine as possibilities. It is indeed remarkable that more than half of the stimulatory effect of 20 AA can be attributed to glutamine, which contributes only 15% to the mixture. Studies of leucine-stimulated insulin release have been very extensive but have resulted in much controversy. It is now understood that leucine has two actions: it is converted to acetyl-CoA and acetoacetate, serving as direct fuel stimulant, or it stimulates GDH allosterically, thus enhancing glutaminolysis with the production of α -ketoglutarate, NAD(P)H, and ammonia. However, beta cells respond to this indirect allosteric effect of leucine only when GDH is sensitized, that

is, when it is not fully inhibited by guanosine triphosphate (GTP) (or ATP) as a result of enhanced glucose metabolism. 20-AASIR may also be mediated, at least in part, by depolarization due to increased Na^+ entry involving Na^+ -dependent transporters, a possibility that has received little attention. Some of this discussion is illustrated in studies with isolated perfused islets by the differential effect that energy run-down has on stimulation of insulin release by glucose, leucine, and α -ketoisocaproate (Figure 3). Isolated rat islets that had been cultured in 10 mM glucose and perfused with 2 mM glutamine show a remarkable change of chemosensitivity of their beta cells as a function of energy depletion with time. They respond well to glucose and α -ketoisocaproate at an early time point when they are totally blind to leucine, but as energy depletion proceeds they respond briskly to all three stimuli. FAs are effective glucose-dependent stimuli of insulin release (FASIR). It is now widely believed that specific metabolic products of FA metabolism play a more important role

Figure 3 Effect of energy run-down on islet chemosensitivity. Isolated rat islets were cultured with 10 mM glucose for 3 days and then perfused with 2 mM glutamine in the absence of glucose for energy run-down periods of 50 min (diamonds) or 120 min (circles) prior to stimulation with (a) 10 mM leucine (Leu), (b) 10 mM glucose (G), and (c) 10 mM α -ketoisocaproate (KIC). Values represent the means $\pm$ SE for 100 islets from three separate perfusions. Reproduced from Li C, Najafi H, Daikhin Y, et al. (2003) Regulation of leucine-stimulated insulin secretion and glutamine metabolism in isolated rat islets. *Journal of Biological Chemistry* 278: 2853–2858.

as signals or coupling factors for secretion than increased generation of ATP by their catabolism. For example, long-chain acyl-CoA and/or diacylglycerol may serve as activators of protein kinase C (PKC). This idea has been expanded, and it is proposed that these and possibly other lipid-derived metabolic coupling factors are critical for GSIR as well. This notion is captured by speaking of the essentiality of FA for GSIR.

Neuroendocrine Modification of Fuel-Stimulated Insulin Release

Eating and digestion of food results in the production of the enterohormones GLP-1 and GIP and also enhances vagal activity, all of which augments fuel-stimulated insulin release. Catecholamines, on the other hand, block secretion very effectively. Recall that neuroendocrine stimulation of beta cells requires glucose. The signaling pathways are well established (Figure 1). The effects are quantitatively very marked, resulting in a left shift and increased magnitude of the fuel dose–response curves for activators and a right shift and decreased magnitude for inhibitors. It is not surprising then, that the pharmaceutical industry is making great strides in taking advantage of these pathways therapeutically.

A Brief Note on Alpha-Cell Function

AA and catecholamines are powerful physiological stimulators of glucagon release from alpha cells, and glucose inhibits these actions. The signaling pathways that operate here are not well understood but may involve steps similar to those described for beta cells, including nucleotide-controlled K^+ channels and L-type Ca^{2+} channels. Much controversy exists about the mechanism(s) of glucose inhibition of glucagon secretion. It has not been determined whether the glucose effects are direct or are mediated by the paracrine actions of insulin, GABA, Zn^{2+} , or other signals. The probable reason for this scanty knowledge lies in the great difficulties that hinder metabolic and other functional studies of alpha cells.

Glucokinase Disease and GDH or K^+ Channel-Linked Hypoglycemia

The biochemical genetic characterization of GK-linked hyper- and hypoglycemia syndromes (collectively termed ‘glucokinase disease’) and of GDH or K^+ channel-linked hyperinsulinemic hypoglycemia has strongly reinforced basic scientific concepts about the role of GK as glucose sensor and other crucial steps in GSIR and AASIR. Nearly 200 GK mutations have been discovered in patients with GK disease, usually inherited as an autosomal dominant trait. Activating mutations cause hyperinsulinemic hypoglycemia because the threshold for GSIR is left shifted as expected, while inactivating mutations cause a mild form of diabetes mellitus (DM) in the case of haploinsufficiency due to a right shift of the glucose threshold. However, severe ketotic permanent neonatal DM (PNDM) ensues when both alleles are strongly affected. In the latter case, beta cells seem to be totally nonfunctional,

and the patients require full insulin replacement therapy right after birth. The syndromes of GK disease are nature’s compelling proof of the GK glucose sensor concept. Activating mutations of GDH, usually explained by loss of GTP (ATP) inhibition of the enzyme, cause hyperinsulinemic hypoglycemia because beta-cell glutaminolysis is enhanced. These patients are also leucine hypersensitive, in agreement with the findings of basic research (see model experiment in Figure 3). Inactivating mutations of one of the subunits of the K^+ channel are a frequent cause of autosomal recessive hyperinsulinemic hypoglycemia. These mutations depolarize the beta cells and result in elevated $[Ca^{2+}]_i$, rendering them supersensitive to AA stimulation and neuroendocrine activation. The hyperresponse to protein meals as observed in these patients is reproduced in isolated perfused islets of sulfonyl urea receptor type 1 (SUR-1) $^{-/-}$ mice that are stimulated by a physiological 20 AA mixture, in contrast to control islets that are refractory to this stimulus in the absence of glucose. There is also increasing support for the view that the highly common E23K polymorphism of the Kir6.2 channel causes a predisposition for the development of T2DM. The E23K mutation increases K^{2+} conductivity and hyperpolarizes beta cells, rendering them less sensitive to physiological stimuli. These examples illustrate how basic and clinical sciences cooperate in their quest to understand glucose homeostasis and its disturbances.

Beta-Cell Therapy in T2DM and Hyperinsulinemia

Our knowledge of physiological chemistry and biochemical genetics of the beta cell has its corollary in beta-cell-based therapeutics of T2DM and hyperinsulinemic hypoglycemia, which contributes substantially to our understanding of islet cell function and glucose homeostasis. The following drugs will be discussed in brief: K^+ channel inhibitors and activators (KCI and KCOs), GK activators (GKAs), GLP-1, GIP, methylxanthines, and muscarinic agonists (see Figure 1). KCIs (i.e., sulfonyl urea derivatives and other chemicals that inhibit the K^+ channel) reduce K^+ conductivity, depolarize the beta cell, and sensitize it to all known physiological stimuli. For decades, they have been the drugs of choice for the treatment of T2DM. KCOs (e.g., diazoxide) hyperpolarize beta cells and have been useful in the treatment of mild forms of hyperinsulinemic hypoglycemia (e.g., due to mutations of GK or GDH). GKAs have been discovered only recently and hold considerable promise for a new approach to the treatment of T2DM. They have effects very similar to those of activating mutations of GK, and it seems that they act by binding to an allosteric activator site of the enzyme (Figure 4). They cause a left shift of the concentration–dependency curve of GSIR and have the additional advantage that they activate hepatic GK and augment glycogen synthesis. It is hoped that ongoing trials in humans will demonstrate the clinical usefulness and safety of this novel, theoretically very attractive, approach to treatment of T2DM. GLP-1 and GIP are obvious candidates for antidiabetic agents as is apparent from Figure 1, and promising trials are underway. M3 agonists that could reproduce the effects of acetylcholine, although potentially useful, have not been explored, most likely because lack of beta-cell specificity might become an issue. Phosphodiesterase inhibitors

Figure 4 Allosteric activator site of the glucokinase glucose sensor molecule: ribbon drawing of the model structure of GK, with the N-terminal to the left and the C-terminal to the right. Glucose, ATP, and Mg^{2+} are located in the substrate cleft of the enzyme, and the allosteric activator site is indicated by several amino acids. The mutation of any one of these (e.g., V62M, I211A, Y214C, M235A, V455M, and A456V) activates the enzyme markedly. Glucokinase activators bind to this site.

(e.g., 3-isobutyl-1-methylxanthine (IBMX)) are powerful potentiators of fuel-stimulated insulin release, but here again it is apparently difficult to design a beta-cell-specific drug. Note that drug treatment of beta cells seems to reduce the diabetes-associated hyperfunction of the glucagon-producing alpha cells as well, thus indirectly enhancing the benefit of antidiabetic drugs with beta-cell action.

Conclusion

This article illustrates that experimental work and mutually corrective or reinforcing dialog between biochemists, geneticists, pharmaceutical chemists, pharmacologists, and the practicing

diabetologists has resulted in a deep understanding of the role that pancreatic endocrine cells play in glucose homeostasis and the pathogenesis of DM and how various therapies might ameliorate the dysfunction of these cells. This remarkable track record bodes well for the future, holding great promise for even deeper insights and the development of new antidiabetic agents and drugs that combat severe hyperinsulinemia.

Glossary

Anabolism The metabolic process through which cells synthesize complex molecules (e.g., proteins) from more simple molecules (e.g., amino acids), usually requiring the consumption of energy, in the form of adenosine triphosphate (ATP).

Autoimmune A state in which the body produces an immune response directed against its own antigens.

Catabolism The metabolic process in which cells break down complex molecules (e.g., proteins) into more simple molecules, with the release of energy.

Cathepsin An intracellular proteolytic enzyme (protease) involved in cellular degradation.

Gluconeogenesis The cellular production of glucose from noncarbohydrate precursors.

Insulin resistance The condition in which cells do not respond to normal concentrations of insulin, resulting in increased secretion of insulin (hyperinsulinemia) to overcome the insulin resistance.

Lipogenesis The cellular synthesis of fatty acids.

Mitogenesis The process of inducing cell division (mitosis).

Transcription factors Proteins that bind to regulatory regions of DNA and regulate the expression of specific genes.

Introduction

Insulin is synthesized and secreted by the pancreatic β cells in response to a variety of signals from nutrients, hormones, and neurotransmitters. Approximately 30–50 units of insulin are secreted daily by the human pancreas. The basal serum insulin concentration is on average 60 pmol l⁻¹, rarely rising over 610 pmol l⁻¹ in normal individuals after eating. Endogenous insulin has a half-life of 3–5 min. It is an anabolic hormone that regulates glucose, lipid, and protein metabolism as well as growth (Figure 1). It exerts these effects by binding to the insulin receptor (IR) that leads to the phosphorylation of molecules and activation of signaling pathways involved in metabolism and mitogenesis. Type 1 diabetes mellitus (T1DM) is a condition of insulin deficiency, due to autoimmune destruction of the pancreatic β cells. A lack of insulin leads to protein catabolism and lipolysis, which is seen in patients with T1DM before commencement of insulin therapy. Conversely, hyperinsulinemia and insulin resistance are seen in the initial stages of type 2 diabetes mellitus (T2DM). Insulin resistance is associated with abdominal obesity, glucose intolerance, dyslipidemia, and hypertension, which are all components of the metabolic syndrome. In addition, insulin resistance is associated with cardiovascular disease, nonalcoholic fatty liver disease, polycystic ovarian syndrome, and certain forms of cancer.

In this article, we focus on the metabolic effects of insulin on protein, lipid, and glucose metabolism. We describe insulin signaling at a molecular level and how defects in insulin signaling can lead to insulin resistance and T2DM.

Insulin Signaling

The Insulin Receptor

The IR is a transmembrane tyrosine kinase receptor. It is a tetramer with two monomers each of which has an α and β subunit linked by disulfide bonds. Each monomer is encoded by one gene that forms a single-chain proreceptor that is

proteolytically cleaved at a furin cleavage site to form the α and β subunits. The α subunits are located extracellularly and are the location of insulin binding. The β subunits span the cell membrane and, on their intracellular portion, contain tyrosine kinase domains flanked by two regulatory regions containing phosphotyrosine-binding (PTB) sites, through which the insulin-signaling cascade is initiated. In its inactive state, the tyrosine kinase activity of the IR is inhibited by an activation loop that prevents substrates from accessing the catalytic site.

The gene for the IR is located on the short arm of chromosome 19. It contains 22 exons encoding the α and β subunits. Transcription of the gene results in two messenger RNA (mRNA) products, due to alternative splicing of exon 11. The translated product without exon 11 is IR-A and the product containing exon 11 is IR-B. IR-A is more prevalent in leukocytes, the fetus, and certain cancers, while IR-B dominates in the liver; both isoforms are found in skeletal muscle and adipose tissue. Signaling through the IR-A receptor leads to cell growth and proliferation, while signaling through IR-B has more metabolic effects. The IR is similar in structure to the insulin-like growth factor-1 receptor (IGF-1R). Although insulin can bind to either the IR or IGF-1R, its affinity for the IR is approximately 1000-fold greater than for the IGF-1R. Of note, hemireceptors (or hybrid receptors) also exist. These receptors are made up of one α and one β subunit from the IR, bound to an α and β subunit from the IGF-1R. These receptors have a low affinity for insulin (Figure 2).

Binding of insulin to the α subunit of the IR leads to a configurational change in the receptor and autophosphorylation of the β subunit tyrosine kinase. In its inactive state, the Tyr 1162 in the activation loop blocks adenosine triphosphate (ATP) binding. Upon insulin binding to the IR, the conformational change in the β subunit allows ATP to bind, leading to phosphorylation of Tyr 1162, followed by phosphorylation of Tyr 1158, and finally Tyr 1163. Phosphorylation of all three tyrosines causes a configurational change that allows ATP free access to the receptor and exposes various sites for interactions with IR substrates (IRSs) and adaptor proteins.

Figure 1 The metabolic effects of insulin acting on the brain, liver, adipose tissue, and skeletal muscle. AgRP, Agouti-related protein; POMC, proopiomelanocortin.

Figure 2 The activation of the insulin receptor splice variants, IGF-1 receptor and insulin/IGF-1 receptor, hybrids by insulin and IGF-1 and the resultant activation of metabolic or mitogenic pathways. Dark green and pink arrows represent strong affinity for the receptor. Pale green arrows represent weak affinity of insulin for receptors.

There are two major pathways that are activated by insulin signaling, the phosphatidylinositol 3-kinase (PI3K) pathway and the mitogen-activated protein kinase (MAPK) pathway; other less well-defined pathways are also activated by the IR tyrosine kinase. The PI3K and Cbl/Cbl-associated protein (CAP) pathways mostly mediate the metabolic effects of insulin, while the MAPK pathway is involved in mitogenesis and growth.

Insulin Signal Transduction

Autophosphorylation of the IR leads to activation of the receptor tyrosine kinase and the phosphorylation of IRS. There are four IRSs, named IRS-1 to IRS-4. The IRSs have a conserved amino terminal region which contains a pleckstrin homology (PH) domain and a PTB domain. These regions interact with the IR. When the IRS proteins are phosphorylated, they attract

Figure 3 Metabolic signaling pathways activated by insulin binding to the insulin receptor. Arrows represent pathways that are activated. Lines ending in circles represent factors that are inhibited by the preceding component in the pathway.

adaptor proteins that contain Src homology-2 (SH2) domains, including growth factor receptor-bound protein 2 (Grb-2), the p85 subunit of PI3K, the tyrosine phosphatase SHP-2, and Grb-associated protein (Gab1), among others. These adaptor proteins then act as docking sites for further downstream effectors (Figure 3).

PI3K signaling

PI3K is composed of a regulatory subunit and a catalytic subunit. The regulatory subunit is 85 kDa and contains SH2 domains that bind to phosphorylated IRS. The catalytic subunit is 110 kDa. Binding of PI3K to IRS leads to the formation of phosphatidylinositol 4,5-bisphosphate (PIP2) and phosphatidylinositol 3,4,5-triphosphate (PIP3). PIP3 is the major product formed. It activates phosphoinositide-dependent kinase (PDK1), the serine/threonine kinase Akt (also called protein kinase B, PKB), and atypical protein kinase C (PKC).

Effects of Akt phosphorylation

Phosphorylated Akt mediates the metabolic effects of insulin signaling through the PI3K pathway. It achieves this by regulating glucose uptake through translocation of glucose transporter 4 (GLUT4) to the cell membrane of skeletal muscle and adipocytes. In addition, Akt alters hepatic glucose synthesis and adipocyte lipogenesis through its effects on certain transcription factors, such as the forkhead box class O1 (FOXO1) transcription factors, peroxisome proliferator-activated receptor gamma (PPAR γ), and the enzyme glycogen synthase kinase-3 (GSK-3). It affects protein synthesis through its interaction with the mammalian target of rapamycin (mTOR) and inhibits apoptotic proteins such as Bcl-2 and Bcl-X_L.

GLUT4 is found in intracellular vesicles of skeletal muscle and fat cells. Translocation of these vesicles to the cell

membrane not only occurs under the influence of insulin, by activation of the PI3K pathway and the Cbl/CAP pathway, but also may occur by mechanisms independent of insulin. Increased GLUT4 expression and translocation to the cell surface enhances the insulin sensitivity of the cell by increasing glucose disposal. The protein Akt substrate of 160 kDa (AS160) has been identified as a Rab guanine nucleotide exchange factor (GAP). The specific Rabs that are substrates for AS160 have also been associated with GLUT4 containing vesicles. In the absence of insulin signaling, the Rab proteins remain inactive, linked to guanosine diphosphate (GDP). When it is phosphorylated by Akt, the GAP activity of AS160 is inhibited and Rab-GTP complexes form. This has been shown in rodent studies to result in GLUT4 vesicle translocation to the cell membrane, through interaction with insulin-regulated aminopeptidase (Irap).

The transcription factor FOXO1 activates genes involved in hepatic gluconeogenesis and inhibits those involved in adipose tissue lipogenesis. In its dephosphorylated state, FOXO1 can enter the cell nucleus and instigates the transcription of genes encoding enzymes essential for gluconeogenesis, such as phosphoenolpyruvate carboxykinase and glucose-6-phosphatase. Therefore, in the fasting state, FOXO1 allows glucose production by the liver. Insulin signaling leads to the phosphorylation of FOXO1 by Akt, preventing its entry into the nucleus leading to downregulation of gluconeogenic genes. PPAR γ coactivator 1 (PGC1 α) is a coactivator of gluconeogenic genes, along with FOXO1 and is also inhibited by insulin signaling.

Lipogenic gene transcription in adipose tissue may be stimulated by PPAR γ . The function of PPAR γ is affected by ligand binding. In the presence of ligand binding, PPAR γ is an activator of gene transcription, but is a repressor in its absence.

The transactivation activity of PPAR γ results from the formation of a complex between PPAR γ and the nuclear receptor retinoid X receptor (RXR). This complex then binds to PPAR response elements on target genes that lead to lipogenesis. FOXO1 inhibits the activity of PPAR γ by two mechanisms: first, by blocking its promoter and second by preventing binding of the PPAR γ /RXR complex to target genes. Phosphorylation of FOXO1, as a result of insulin signaling, releases its inhibition of PPAR γ and results in the transcription of lipogenic genes. In the absence of ligand binding, PPAR γ may cause transrepression of other genes, by interfering with other transcription factor pathways, such as those related to nuclear factor kappa B (NF- κ B) mediating the anti-inflammatory effects of PPAR γ .

Hepatic and skeletal muscle glycogen synthesis is also affected by Akt phosphorylation. Glycogen synthase kinase-3 (GSK-3) is a constitutively active kinase that is inactivated by insulin signaling. GSK-3 causes phosphorylation of serine residues at the carboxyl terminus of glycogen synthase, inhibiting its ability to convert glucose residues to glycogen. Insulin activation of Akt leads to dephosphorylation and inactivation of GSK-3, preventing phosphorylation of glycogen synthase. In addition, insulin signaling activates protein phosphatase 1 (PP1), which dephosphorylates glycogen synthase. Increased GSK-3 expression and activity in skeletal muscle has been reported in insulin resistance and T2DM. Pharmacological inhibitors of GSK-3 are under investigation as treatment options for T2DM. GSK-3 also regulates protein synthesis by phosphorylating elongation initiation factor 2B (eIF2B). During initiation of translation, eIF2 brings tRNA_m^{Met} (methionine transfer RNA) to the 40S subunit of the ribosome. eIF2 is associated with GTP, which is hydrolyzed to GDP on binding to tRNA_m^{Met} to the start codon. eIF2B is the guanine nuclear exchange factor for eIF2, converting eIF2-GDP to eIF-GTP. Phosphorylation of an amino terminus serine on eIF2B by GSK-3 inhibits the conversion of eIF2-GDP to eIF2-GTP; thereby, GSK-3 prevents the initiation of translation and protein synthesis. By phosphorylating GSK-3, insulin signaling disrupts the inhibitory activity of GSK-3 on protein synthesis.

Insulin-mediated protein synthesis is also mediated by mTOR in the presence of amino acids. mTOR is a serine/threonine kinase that targets the ribosomal protein kinase S6 kinase (S6K) as well as the eukaryotic initiation factor 4E (eIF4E)-binding protein1 (4E-BP1). S6K and 4E-BP1 regulate the initiation of ribosomal translation of specific mRNA populations. mTOR is activated by insulin signaling and phosphorylation of Akt in the presence of nutrients, such as amino acids. Its activity is inhibited by the tuberous sclerosis 1 (TSC1) or hamartin and TSC2 or tuberlin protein complex (TSC1/TSC2). The TSC1/TSC2 complex has GTPase activity toward the small GTPase Rheb, which inhibits its activity. Rheb activates mTOR. Akt phosphorylates TSC2 at Ser939 and Thr1462, leading to loss of the inhibition of the TSC1/TSC2 complex on Rheb and therefore mTOR is activated. Increased mTOR activity allows phosphorylation of S6K and 4E-BP1 and protein synthesis. The absence of cellular nutrition leads to an increase in the adenosine monophosphate (AMP)-to-ATP ratio, with a decrease in protein, lipid, and glycogen synthesis and an upregulation of catabolic pathways with the purpose of generating ATP.

AMP activates the activity of AMP-activated protein kinase (AMPK) by phosphorylation of Thr172 in its catalytic α subunit. AMPK possesses regulatory β and γ subunits in addition to the catalytic subunit; it phosphorylates TSC2 at Thr1227 and Ser1345, sites distinct from those phosphorylated by Akt. Phosphorylation of TSC2 by AMPK increases the GTPase activity of the TSC1/TSC2 complex on Rheb, inhibiting its activity and preventing mTOR activation. AMPK may also phosphorylate mTOR directly at Thr2445, therefore decreasing downstream activity of S6K and 4E-BP1. Activated mTOR and S6K also inhibit IRS-1 and IRS-2 through serine phosphorylation, providing a negative feedback control. Certain tumor suppressor genes such as phosphatase and tensin homolog deleted on chromosome 10 (PTEN) and serine/threonine kinase 11 (STK11) regulate this pathway. Loss of their activity can lead to constitutive activity of mTOR signaling and tumor formation.

Signaling through the PI3K pathway also leads to the phosphorylation of elements involved in the inhibition of apoptosis. Bcl-2 and Bcl-X_L are anti-apoptotic proteins. When they are complexed to Bcl-2/Bcl-X_L antagonist of cell death (BAD), their anti-apoptotic effect is inhibited and apoptosis is promoted. BAD is serine phosphorylated both by PI3K activation of Akt and through the MAPK pathway. Phosphorylation of BAD leads to dissociation from Bcl-2 and Bcl-X_L, thereby inhibiting apoptosis. Therefore, insulin may inhibit cellular apoptosis.

The Cbl/CAP pathway

Glucose uptake has also been reported to be affected by the Cbl/CAP pathway. The IR recruits the adaptor protein CAP, which in turn binds to the oncogene Cbl. After phosphorylation of Cbl, the CBL-CAP complex dissociates from the IR and forms a ternary complex with the caveolar protein flotillin, leading to localization of the CAP/Cbl complex to a lipid raft domain of the plasma membrane. This translocation leads to recruitment of the adaptor protein CrkII, which then forms a complex with the guanyl nucleotide exchange protein C3G. C3G comes into proximity with the G protein, TC10, and catalyzes the exchange of GTP for GDP. This process leads to GLUT4 vesicle translocation to the cell membrane through its activity on actin. The strength of this activated pathway on GLUT-4 translocation compared with the canonical Akt pathway is not well defined.

MAPK signaling

The MAPK pathway is activated by growth factor Grb2 binding to phosphorylated Shc or IRS. Grb2 is bound to the mammalian Son of Sevenless (mSOS), which results in the activation of Ras. Ras (like Rab) is a GTP-binding protein that transmits signals when bound to GTP and is inhibited by GTPase. Activated Ras binds to the inner plasma membrane and the serine/threonine kinase Raf, leading to the phosphorylation of Raf, which in turn leads to activation of the MAP/extracellular signal-regulated kinase (ERK) kinases MEK1 and MEK2, in turn causing phosphorylation of ERK1 and ERK2. ERK1 and ERK 2 phosphorylate transcription factors, including cAMP response element binding protein (CREB), c-Myc, and c-Fos, leading to the growth effects of insulin. In addition to the canonical MAPK pathway, other MAPK pathways such as the

p38 and c-jun N-terminal kinase (JNK) pathways may also be important in insulin's biological effects, but are less well defined.

Regulation of Insulin Signaling

The PI3K and MAPK pathways can interact via their downstream signaling mediators and are also regulated by other molecules, such as cytokines. PI3K and MAPK pathways can activate each other as Akt can activate Raf kinase and Ras can activate PI3K. However, PI3K signaling can also feed back on IRS-1, to inhibit further insulin signaling.

Serine phosphorylation of IRS-1 is an important regulatory step in inhibition of insulin signaling, in normal and pathological circumstances. In rodents, Ser307 is part of the PTB domain of IRS-1 and equates to the Ser312 in humans. Phosphorylation of Ser307 in rodent studies has been seen to prevent tyrosine phosphorylation of IRS-1. This is a mechanism by which mTOR, atypical PKC, GSK-3, tumor necrosis factor- α (TNF α), and JNK inhibit insulin signaling. It is also the method by which PI3K can negatively feed back on IRS-1. IRS-1 may also undergo serine phosphorylation at the SH2 domain, under the influence of Erk1/2, disrupting its activity. Cytokines and the suppressor of cytokine signaling (SOCS) can also increase proteasomal degeneration of IRS-1. IRS-1 activity may also be inhibited by Raf, which displaces IRS-1 bound to PI3K, inhibiting downstream signaling. In addition to their effects on IRS-1, cytokines can interfere with insulin signaling by their action on the IR. SOCS-3 can bind to the IR-binding site for IRS-1, therefore inhibiting its association with the IR, where inhibitory feedback mechanisms may be involved in the development of impaired insulin signaling in insulin resistance.

Metabolic Effects of Insulin

The metabolic effects of insulin are primarily seen in the liver, skeletal muscle, and adipose tissue. In adipose tissue and skeletal muscle, insulin increases glucose uptake through GLUT4, which as described above is under the influence of insulin signaling, primarily through the PI3K pathway. In the liver, the GLUT2 transporter is not under the influence of insulin. Instead, the rate of glucose uptake is determined by the rate of glucose disposal through glycolysis and glycogen synthesis. Insulin promotes both of these pathways by activating the enzymes glucokinase, glycogen phosphorylase, and glycogen synthase. At the same time, gluconeogenesis gene transcription is inhibited by Akt phosphorylation of FOXO1. In skeletal muscle, as in the liver, insulin promotes glycogen synthesis through dephosphorylation of glycogen synthase. In adipose tissue, glucose is used to form glycerol-3-phosphate which is involved in the esterification of free fatty acids (FFAs) to triglycerides (TGs).

Insulin inhibits lipolysis in adipose tissue by dephosphorylating and inactivating hormone-sensitive lipase which is responsible for hydrolysis of stored TG into FFA and glycerol. Dephosphorylation of hormone-sensitive lipase is mediated by protein phosphatase and phosphodiesterase, under the influence of insulin. At the same time, insulin promotes the

activities of endothelial-bound lipoprotein lipase that leads to removal of FFA from circulating very low density lipoprotein (VLDL) and activates lipogenesis, causing FFA to be esterified into TG in the presence of glycerol-3-phosphate. Overall, these effects of insulin in adipose tissue decrease circulating FFA and therefore limit the substrate provided to the liver for VLDL and ketone formation. In addition to decreasing the FFA supply to the liver, ketogenesis is also inhibited by the actions of insulin on hepatic acetyl coenzyme A (CoA) carboxylase. Dephosphorylation of hepatic acetyl CoA carboxylase leads to increased malonyl CoA formation, which inhibits carnitine palmitoyl transferase-1 (CPT-1), the shuttle for long-chain fatty acids across the outer mitochondrial membrane. Inhibition of CPT-1 prevents long-chain fatty acids from being transported into the mitochondria for β oxidation and ketogenesis. Insulin also activates the sterol regulatory element-binding protein (SREBP) 1c which is a transcription factor involved in hepatic FFA and cholesterol synthesis.

In skeletal muscle, insulin signaling in the presence of nutrients promotes protein synthesis through mTOR signaling. Insulin also inhibits protein catabolism by decreasing the activity of cathepsins, proteases that are found in lysosomes and by also stabilizing lysosomal membranes.

Insulin signaling in the brain leads to alterations in energy intake and body weight. This has been demonstrated in rodents and primates, where intracerebral insulin infusions led to decreased food intake and reduced body weight, attributed to insulin signaling in the hypothalamus. IRs in the brain are concentrated in the arcuate nucleus of the hypothalamus which contains neurons that produce neuropeptide Y (NPY), Agouti-related protein (AgRP), and pro-opiomelanocortin (POMC). Activation of the hypothalamic IRs leads to signaling through the PI3K pathway and activation of K_{ATP} channels, resulting in decreased production of NPY and AgRP and increased production of POMC. POMC is a precursor of α -melanocyte-stimulating hormone that binds to melanocortin receptor 3 (MCR3) and melanocortin receptor 4 (MCR4) and causes decreased appetite. NPY activates the Y receptors, while AgRP antagonizes MCR3 and MCR4, both of which stimulate appetite. Cerebral insulin signaling through the PI3K pathway also increases hepatic glucose uptake and decreases hepatic gluconeogenesis. The pathways through which this occurs are undergoing investigation, but it appears to be partly by the autonomic nervous system, in addition to increased interleukin-6, as a result of decreased AgRP, leading to decreased glucose-6-phosphatase expression. Rodent models also suggest that cerebral insulin signaling promotes adipocyte lipogenesis and is the subject of ongoing research (Figure 1).

Insulin Resistance

Insulin resistance is associated with obesity, dyslipidemia, hypertension, and T2DM. Hyperinsulinemia usually precedes the development of insulin resistance. In normal individuals, insulin is released in two phases after ingestion of nutrients. There is a first-phase insulin response which occurs rapidly and a second-phase insulin response which occurs after about 20 min, when the first-phase response disappears. Early in development of insulin resistance and T2DM, loss of the first-phase insulin response is seen, followed by an exaggerated

second-phase response. This subsequently leads to chronic hyperinsulinemia and insulin resistance develops when tissues demonstrate a decreased response to insulin. Insulin resistance results in increased circulating levels of glucose and FFA, dyslipidemia, and increased inflammatory cytokine activity.

Rodent studies of insulin resistance and T2DM have suggested that insulin-signaling abnormalities may occur due to decreased cellular IR content, an increased number of IR/IGF-IR hybrids, and increased serine/threonine phosphorylation of IRS-1. Hyperinsulinemia has also been shown to increase proteasomal degradation of IRS-1.

Insulin resistance in adipose tissue leads to increased lipolysis and FFA production, with loss of inhibition of hormone-sensitive lipase and decreased activity of lipoprotein lipase. Increased FFAs have been seen to cause defects in IRS-1 activation of the PI3K pathway. Inability of the adipose tissue to esterify FFA leads to accumulation of metabolites involved in TG formation in the liver and skeletal muscle. These metabolites include long-chain acyl CoA, diacylglycerol (DAG), and ceramide. The final step in TG formation is the conversion of DAG to triacylglycerol by DAG acyltransferase-1. DAG is a potent activator of PKC θ which impairs insulin signaling in skeletal muscle. Rodent studies have also demonstrated that after lipid infusion, PKC θ activity was associated with decreased tyrosine phosphorylation of IRS-1. Inactivation of PKC θ in mice prevents lipid-induced defects in insulin signaling and glucose transport in skeletal muscle. In studies on the Zucker rat, ceramide has been shown to inhibit insulin signaling and Akt activation; it also inhibits insulin-mediated glucose uptake and glycogen synthesis. Although in humans, lower ceramide is seen in insulin-sensitive individuals, and elevated levels of DAG have been seen in obese diabetic individuals, their exact association with and role in insulin resistance in humans are unclear.

FFAs also increase inflammatory cytokines by signaling through the toll-like receptor 4 (TLR4). TLR4 is a transmembrane receptor with an intracellular domain that is homologous to the interleukin-1 receptor (IL-1R). Signaling through the TLR4 and IL-1R leads to activation of the transcription factor NF- κ B pathway and transcription of proinflammatory cytokines and chemokines, such as JNK and inhibitor of NF- κ B kinase (IKK). Inflammatory cytokines such as TNF α and SOCS proteins can lead to defects in the insulin-signaling pathway by serine phosphorylation of IRS-1 and interference with IR binding to IRS-1. JNK and IKK also cause serine phosphorylation of IRS-1 and contribute to insulin resistance.

Inhibition of insulin signaling leads to increased activation of the transcription factors FOXO1 and SREBP1c, with increased expression of genes for gluconeogenesis and lipogenesis. In the liver, this results in increased glucose and VLDL formation in the presence of elevated FFAs. PPAR γ expression is then inhibited by the activation of FOXO1 and TNF α . These abnormalities

in glucose and lipid formation result in hyperglycemia and elevated FFAs that have been shown to be toxic to the pancreatic β cell and lead to impaired insulin secretion and the development of T2DM.

Conclusions

This article describes the importance of insulin signaling in the regulation of human metabolism. Insulin is a key hormone in integrating and controlling the responses of organs to nutritional intake. We discuss the signaling pathways involved in normal insulin action and the abnormalities that may develop and lead to the development of insulin resistance.

Glossary

Cytoplasmic tail Intracellular portion (20–60 amino acids) of integrins involved in signaling.

Cytoskeleton Structural network of actin microfilaments, keratin intermediate filaments, and tubulin microtubules in mammalian cells.

Extracellular matrix (ECM) Dense array of fibrillar proteins, enzymes, and other molecules that provides a scaffold for cells and tissues, and contains binding sites for integrins.

Focal adhesion Dash-like cell–matrix adhesion site consisting of a cytoplasmic multiprotein complex surrounding a core of clustered integrins.

Integrin ligand ECM protein that binds the extracellular head domain of integrins.

Metal ion-dependent adhesion site (MIDAS) Array of key residues in some integrin head domains which coordinates a divalent cation during ligand binding.

NPxY Conserved sequence in most integrin β -tails that serves as a docking site for signaling molecules.

Phosphotyrosine-binding (PTB) domain Structurally conserved domain in integrin β -tail-binding proteins, which binds the β -tail to regulate signaling.

Integrin Overview

Integrins are transmembrane receptors that promote cellular attachment to the extracellular matrix (ECM) and counter-receptors on the surfaces of neighboring cells. Integrins are responsible for mediating cell adhesion and migration, and for maintaining tissue integrity. They are expressed at the surface of virtually all multicellular animal cells as noncovalent heterodimers of α - and β -subunits. Integrins are named based on their α - and β -subunit composition, for example, $\alpha_1\beta_1$ and $\alpha_{IIb}\beta_3$.

The integrin family in humans consists of 18 α - and 8 β -subunits, each of which is encoded by unique genes. Each α -subunit pairs with a restricted set of β -subunits, resulting in a total of 24 known functional integrin heterodimers. Each pairing, in turn, is expressed on a limited array of cell types. Thus, each cell type has its own particular repertoire of integrins. Since different integrins display distinct ligand-binding preferences, these repertoires specify adhesive preferences of different cell types. In some cases, multiple integrins can recognize the same ligand. For example, many integrins bind to the ECM protein, fibronectin. Even within the same ECM protein, integrins can vary in recognition specificity. Integrin $\alpha_v\beta_3$, for example, binds to an Arg–Gly–Asp (RGD) motif in fibronectin, while integrin $\alpha_4\beta_1$ binds to a Leu–Asp–Val (LDV) motif present in a different part of fibronectin. Furthermore, these short peptide motifs can occur in evolutionarily unrelated proteins, where they can serve as recognition sites for many different integrins. The RGD motif occurs in many proteins and can bind to many integrins (e.g., $\alpha_{IIb}\beta_3$, $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$). This integrin-binding motif interaction is conserved in phylogeny; for example, the *Drosophila* PS2 integrin recognizes an RGD sequence in tiggrrin, a matrix protein. The occurrence of integrin-binding motifs, such as RGD, is an example of convergent evolution dictated by the recognition specificity of adhesion receptors.

All integrin subunits possess a single transmembrane domain (TMD), which separates the large extracellular, N-terminal ligand-binding head domain from the typically short (less than 60 amino acids) C-terminal cytoplasmic tail domain. Besides acting as cellular glue to support adhesion, and as feet to facilitate migration, integrins initiate transmembrane signals, which regulate processes such as embryogenesis, cell development, proliferation, apoptosis, and the immune response.

General Features of Integrin Signaling

Integrins derive their name from their role of integrating the ECM with the insoluble cellular skeleton (cytoskeleton). Binding of ligands to the extracellular portion of integrins leads to both conformational changes in the receptors and to receptor clustering. This combination of events initiates intracellular signals such as protein tyrosine phosphorylation, activation of small GTPases (guanosine triphosphate-hydrolyzing enzymes), and changes in phospholipid biosynthesis. This process is commonly referred to as ‘outside-in’ signaling. In addition, integrins are subject to the so-called ‘inside-out’ signaling. Integrins can fluctuate between three functional states – an active state that manifests high affinity for binding ligands, a high-affinity state that is bound to ligand, or in a distinct inactive state, which has a low affinity for ligands. Inside-out signaling is defined as modulation of the functional state of integrins via intracellular signaling processes. It is frequently mediated by interactions of intracellular components with the integrins’ cytoplasmic tails. Furthermore, signals from one integrin can regulate the activation state of another in a phenomenon referred to as ‘integrin transregulation’ or ‘cross-talk’. Through transregulation, multiple integrins can be linked via a combination of both outside-in and inside-out signaling.

Inside-Out Signaling

Modulation of integrin function can occur by changes in ligand-binding affinity or by changes in the clustering of these receptors. The former mechanism is often referred to as integrin activation and the latter as a change in avidity. These functional changes can be caused by signaling pathways initiated by agonist–receptor interactions at the plasma membrane. The appropriate regulation of integrin activation is required for the formation and maintenance of normal tissue architecture.

Physiological Roles of Inside-Out Signaling

Integrin activation in hematopoietic cells

Integrin activation plays a crucial role in the biology of blood cells. For example, the platelet integrin, $\alpha_{IIb}\beta_3$, is usually maintained in the inactive state, with very low affinity for its extracellular ligands, fibrinogen, fibronectin, and von Willebrand factor. Upon platelet stimulation, the integrins are quickly activated, leading to fibrinogen binding and consequent platelet aggregation, an early step in hemostasis. Thus, the loss of $\alpha_{IIb}\beta_3$ integrin activation impairs hemostasis. Conversely, platelet aggregation is central in arterial thrombosis that is responsible for the majority of heart attacks and strokes. Pharmacological blockade of activation of integrin $\alpha_{IIb}\beta_3$ by agents such as aspirin or ticlopidine is therefore often used to treat patients at risk for these diseases. Similarly, rapid activation of dormant integrins on leukocytes allows these cells to attach firmly to the endothelial vessel wall and resist strong shear forces from the flowing blood. This step is essential for their migration into sites of inflammation. For this reason, loss of leukocyte integrin activation can lead to enhanced susceptibility to infections, and its blockade may be useful in anti-inflammatory therapies.

Integrin activation in tissues

For adherent cells in tissues, such as fibroblasts or epithelial cells, stable cellular attachment to the ECM is necessary for maintaining tissue integrity. Many of the best-studied integrins in these cells, such as the α_5 , α_v , and α_6 integrins, are indispensable components of cell–substrate attachment structures – focal adhesions, hemidesmosomes, and podosomes. In addition to attaching to the ECM, integrins participate in formation and remodeling of the ECM. Activation of tissue integrins can regulate the assembly and structure of the ECM and control the stability of integrin–matrix attachments. In addition, the migration of these cells in tissues is regulated by the ability of integrins to become activated. Furthermore, integrin activation may be topographically localized across the basal cell surface. For example, activated $\alpha_v\beta_3$ integrins are preferentially localized to the leading edge of migrating endothelial cells and during neurite outgrowth.

Integrin Activation

The switch from an inactive to an active state is the result of alterations in the conformation of the integrin extracellular domains. These conformational changes can be triggered by protein–protein interactions at the integrin cytoplasmic face.

These protein–protein interactions are regulated by different signaling pathways in different cells. For example, activation of Raf-1 kinase often suppresses integrin activation, whereas activated R-Ras GTPase can antagonize Raf-1-mediated suppression. However, in many contexts, activation of key intermediates such as the GTPase Rap1, or protein kinase C, promotes increased integrin affinity. In this model, protein kinase C or another upstream intermediate induces the conversion of Rap1 to its active state and its enrichment at the plasma membrane, nucleating an integrin-activating complex. Membrane-tethered Rap1 then binds Rap1-interacting adapter molecule (RIAM1), a scaffolding molecule, which also binds the cytoskeletal linker protein talin. In this fashion, talin is recruited to the plasma membrane where it participates directly in integrin activation (see section [Tail-Binding Proteins](#)). Whatever the upstream events, it is now clear that the final common events involve changes in interactions at the integrin cytoplasmic domain ([Figure 1](#)).

Contribution of cytoplasmic domains: membrane-proximal residues

Deletion of the tail sequences adjacent to the putative transmembrane regions in either the α - or β -tail can activate integrins, indicating that these residues are essential for maintaining integrins in an inactive state. One model for activation entails breaking of a salt bridge in this region that holds the tails together, leading to an opening of the tails via a scissor-like mechanism ([Figure 1](#)). This leads to an allosteric rearrangement in the extracellular domain and a shift to the active state.

Transmembrane domain conformational changes

The allosteric rearrangements of integrin extracellular domains, which are initiated by interactions at the tail domains, are propagated through the integrin TMDs. Thus, the TMDs play critical roles in controlling the activation states. For most integrins in the low-affinity state, the α -subunit TMD is maintained orthogonal to the plane of the plasma membrane, whereas the β -subunit TMD is held at a 25° tilt angle. Electrostatic interactions between these domains, particularly involving conserved

Figure 1 Inside-out signaling activates integrins. Binding of an integrin-activating complex (IAC), which includes talin, to the cytoplasmic tails of an integrin heterodimer produces conformational changes in the extracellular head domains, leading to activation and high-affinity binding to ligand (L).

clasp residues, appear important for keeping integrin head domains in the inactive conformation. Inside-out signaling causes a breaking of the inner-membrane clasps, resulting in shifting of the relative orientations of the TMDs and subsequent allosteric rearrangements of the extracellular domains.

Extracellular domain conformational changes

Precise conformational shifts at the ligand-binding face of integrins result in high-affinity binding to ligands. Integrin–ligand interactions require an essential Asp or Glu residue in the integrin recognition sequence in the ligand, as well as the presence of a divalent cation. Some of the integrin α -subunits have an inserted or I/A domain near the N-terminus; these integrins contact ligand solely through the α -subunit, although the β -subunit plays an accessory role. The I/A domain manifests a metal ion-dependent adhesion site (MIDAS). Key residues in the ligand cooperate with the MIDAS to coordinate the cation and allow integrin–ligand interaction. Conformational changes in the MIDAS during cation coordination and ligand binding subsequently result in secondary changes in the rest of the integrin, including a downward shift of a α -helix C-terminal to the I/A domain, thereby switching the integrin from the closed inactive state to the open active state. For integrins with an α -subunit that does not contain an I/A domain, the I/A-like domain in the β -subunit cooperates with the α -subunit in a somewhat different fashion to mediate ligand interaction, and also through coordination of a divalent cation.

The global structure of an inactive integrin extracellular domain may be a bent conformation, in which the I/A or I/A-like domain and associated head region are held in close proximity to the outer membrane, due to an acute bend in the outer membrane-proximal segments of the integrin subunits. Inside-out signaling appears to induce a straightening of the extracellular domains into an extended structure, which likely represents the intermediate, active state in the absence of bound ligand. The fully extended, open conformation is finally adopted as the active integrin engages the ligand molecule.

Tail-binding proteins

Numerous cytoplasmic integrin-binding proteins have been described, and several have been reported to contribute to activation through binding to the integrin tails. As mentioned above, the best-characterized example is talin, which promotes integrin activation by binding to a subset of integrin β -subunit tails at a highly conserved NPxY motif. Mutational evidence suggests that integrin α – β -subunit tail interactions inhibit activation. The ability of talin to activate the integrins has been attributed to competition with the α -subunit for β -tail binding, whereby talin forms a salt bridge with the β -tail, displacing the α -subunit tail. A segment of the talin head domain binds to the membrane-distal NPxY motif via its phosphotyrosine-binding (PTB) domain, which, combined with a secondary binding step at a membrane-proximal site, allows talin to disrupt tail α – β -subunit interactions to stimulate integrin activation.

Talin binding to the integrin β -tail is both necessary and sufficient for integrin activation. However, in addition to talin, other integrin- and talin-binding proteins contribute to integrin activation in the cellular context. Kindlins are a small family of integrin-binding proteins which interact with β -tails at an NxxY/F motif distinct from the NPxY talin-binding motif.

Kindlin binding to β -tails can enhance talin-mediated integrin activation, and other as yet unidentified proteins may be found to associate with this integrin-activating complex.

Negative regulation

Whereas the talin-centered integrin-activating complex promotes formation and maintenance of the high-affinity state of integrins, competing inside-out mechanisms suppress activation or cause reversion to the inactive state, principally by preventing or disrupting talin–integrin interactions. Integrin-binding proteins such as filamin, and a class of PTB-domain-containing proteins including Numb, Dok-1, and ICAP1 (integrin cytoplasmic domain-associated protein-1) may turn integrins off by binding the β -tail and displacing talin; similarly, phosphatidylinositol phosphate kinase type 1 γ -90 can affect the same outcome by binding to talin. Other mechanisms, such as β -tail phosphorylation by Src kinase, also contribute to negative regulation. Furthermore, endocytic recycling of integrins provides an additional layer of regulation of the concentration of available receptors at the plasma membrane.

Avidity modulation

In addition to affinity modulation through conformational changes in individual integrin molecules, cell adhesion can also be enhanced by increasing the density of ligand-binding sites through integrin clustering, via an affinity-independent mechanism known as ‘avidity modulation’. Many integrin ligands are multivalent; thus, integrin clustering can promote adhesion through cooperative ligand binding. In many cases, a combination of both affinity and avidity modulation contributes to the regulation of cell adhesion.

Outside-In Signaling

Occupancy of integrins leads to conformational changes that can propagate over long distances in the extracellular domain. It has been proposed that these allosteric rearrangements can be transmitted across the plasma membrane, changing the interactions of the α and β cytoplasmic domains with each other and, thus, the integrin’s interactions with intracellular signaling molecules. Furthermore, occupancy leads to integrin clustering, which can also change the physical relationships of the integrin cytoplasmic domains with each other. This combination of occupancy and clustering is believed to initiate signals from integrins. These signals regulate the formation and strengthening of adhesion sites, the dynamics of cytoskeletal structure, cell shape and size, and cell polarity and cell migration. In addition to controlling the physical activities of cells, signaling through integrins also regulates gene expression, cell proliferation, and apoptosis, and many integrins are required for the development of particular lineages.

Integrins in Adhesion Sites

Most integrins are physically linked to the actin cytoskeleton via interactions of the β -tail with actin-binding proteins such as α -actinin, talin, and filamin. The $\alpha_6\beta_4$ integrins associate with the intermediate filament cytoskeleton through other linker proteins – BP180 (BPAG2), BP230 (BPAG1), and plectin. By

Figure 2 Focal contacts and hemidesmosomes. Two types of integrin–ECM contacts are shown. (a) Focal contacts are visualized by labeling $\alpha_{11b}\beta_3$ integrin clusters in a fibroblast expressing $\alpha_{11b}\beta_3$ attached to fibrinogen. Arrowheads indicate two focal contacts. (b) Transmission electron micrograph of a cross section of bovine tongue. Hemidesmosomes (arrowheads) are seen as electron-dense structures at the basal surface of the tongue epithelial cells (ECs), connecting the intermediate filaments (arrow) to the ECM. Courtesy of Gregory W. deHart and Jonathan C.R. Jones.

connecting the ECM with the cytoskeleton, clustered integrins form the essential core of complexes of structural and signaling molecules, such as focal complexes and adhesions (contacts), hemidesmosomes (specific to epithelial cells, they contain $\alpha_6\beta_4$ integrin and are linked to intermediate filaments), osteoclast and macrophage structures called podosomes (which have many of the same protein components as focal adhesions), and adhesion sites in invadopodia in cancer cells (Figure 2).

Formation of adhesion sites

Ligand binding and integrin clustering nucleate nascent cell adhesion sites. Numerous cytoskeletal adapters and signaling molecules are subsequently recruited to the clustered integrin tails. These complexes serve as the initiation points for signaling by integrins to affect cellular phenotypes. Focal complexes mature to become focal adhesions (focal contacts) as more integrins and signaling molecules associate, thereby strengthening cellular attachments to the ECM.

Regulation of adhesion dynamics

Adhesion sites are dynamic structures which undergo remodeling to fit the needs of the cell or of the region of the cell in contact with the ECM. Focal complexes form at the leading edges of lamellipodia and filopodia in migrating cells, where they mediate new attachments, but do not mature to focal adhesions. Instead, these smaller complexes are subject to rapid turnover, as the cell continues to extend protrusions in the direction of migration. Concomitantly, integrins in focal adhesions at the rear of the cell are recycled to the front via a treadmill-like mechanism. Focal adhesions, hemidesmosomes, and podosomes break apart and reform by severing and re-establishing integrin–ECM contacts, under conditions in which cells are motile, such as during development and in wound healing.

Contributions to Cellular Phenotypes

Connections to intracellular signaling pathways

Although integrins themselves do not manifest any catalytic activity, they transmit signals through binding partners such as integrin-associated protein (IAP, CD47), integrin-linked kinase (ILK), focal adhesion kinase (FAK), Src and Syk kinases, and

members of the tetraspanin transmembrane protein family. Integrin ligation activates members of the Ras family of GTPases, and can also lead to activation of kinases such as Jun-kinase (JNK), p21-associated kinase (PAK), and extracellular signal-regulated kinase (ERK) (microtubule-associated proteins) kinase – the latter two are localized to integrin-rich adhesion sites. These enzymes can subsequently regulate the expression of genes involved in cell proliferation and differentiation. Furthermore, integrins play a role in the inhibition of detachment-induced apoptosis, called ‘anoikis’, through regulation of the PI3-kinase/Akt signaling pathway.

Effects on the cytoskeleton

By connecting the ECM to the intracellular cytoskeleton, integrins also act as mechanosensors, transmitting information about the physical state of the ECM into the cell and altering cytoskeletal dynamics. Integrin ligation can lead to activation of small GTPases of the Rho family, particularly RhoA, Cdc42, and Rac, which promote cytoskeletal rearrangements leading to the formation of actin stress fibers, filopodia, and lamellipodia, respectively. Within focal adhesions, integrins can activate kinases important for downstream signaling, such as FAK and Src tyrosine kinases. Activation of these enzymes results from signals initiated at the integrin cytoplasmic tails. Src interacts directly with the β_3 -tail and is a key player in outside-in signaling. By binding and phosphorylating its proximal substrates such as FAK, p130Cas, Syk, and paxillin, Src acts as a master conduit for outside-in integrin signaling to regulate Rho and Ras GTPases and their effects on the cytoskeleton, adhesion sites, and gene expression. Integrin tails also affect cytoskeletal rearrangements through other mechanisms, for example, activation of Syk tyrosine kinase through its direct binding to the β_3 -tail, which promotes Vav1-induced GTP loading of Rac and subsequent lamellipodial formation. Through such mechanisms, integrins regulate cell polarity, migration, shape and size, and ECM assembly.

Integrin Cross-Talk

Ligand binding to one subtype of integrins can affect the activation state of another integrin subtype on the same cell, by modulating the ligand-binding affinity and/or avidity of that integrin. For example, outside-in signaling through ligand binding of $\alpha_4\beta_1$ integrin can affect $\alpha_1\beta_2$ -dependent lymphocyte adhesion and migration by regulating signaling through $\alpha_1\beta_2$. Similarly, cross-talk signaling between $\alpha_v\beta_3$ and $\alpha_5\beta_1$ integrins in endothelial cells regulates angiogenic responses. Furthermore, integrins are involved in cooperative signaling with other nonintegrin receptors, such as the epidermal growth factor (EGF) receptor and the T-cell receptor complex.

Summary

Integrins have lived up to their name, acting as a unique class of receptors which integrate bi-directional informational cues between the extra- and intracellular environments. On both sides of the plasma membrane, dynamic protein interactions with the integrin head and tail domains combine with mechanical forces to couple outside-in with inside-out

Figure 3 Interplay between outside-in and inside-out integrin signaling. Inside-out signaling converts integrins from a low-affinity to a high-affinity state by interactions of the tail domains with intracellular proteins such as talin. Through activation of the head domains, binding to ligand (L), and receptor clustering, integrins remodel the ECM and dynamically regulate cell adhesion and migration. Conversely, outside-in signaling creates binding sites on the cytoplasmic face of activated integrins to bind proteins and transmit signals to the cell interior, resulting in changes to the cytoskeleton, gene expression, and cell survival.

signaling. Structural rearrangements in the ligand-binding or cytoplasmic faces of integrins are propagated allosterically through shifts in the TMDs. Precise control of the integrin activity and avidity states allows these signaling conduits to regulate cellular and physiological responses in a wide variety of contexts (Figure 3). As the list of integrin-binding proteins

and mechanistic insights grows, the scope of outside-in and inside-out integrin signaling continues to expand.

Glossary

Connexon One of six protein subunits that aggregate to form a central channel and one-half of a gap junction (hemi-channel) in the cell membrane. There are a variety of different connexons and their varied structure determines the overall properties of the hemi-channel. A complete gap junction spans across the membrane of two closely adjacent cells by the alignment of two hemi-channels.

Electrotonic communication The passive spread of an electrical charge (without amplification) from the source of the electrical change (e.g., membrane depolarization of a cell) through adjacent cells. The distance and speed of transmission depend on the electrical resistance of the tissue. Open gap junctions between cells have low electrical resistance and facilitate the spread of electrical signals.

Ionotropic receptor A receptor that has ion channel properties and responds to agonist stimulation by the opening of the channel component to induce changes in membrane potential.

Luciferase-based luminometry A bioassay designed to measure adenosine triphosphate (ATP) concentrations based on the numbers of photons released by the enzyme luciferase during the utilization of ATP in chemical reactions.

Metabotropic receptors Receptors that do not directly open ion channels but often respond to agonist stimulation by the formation of a second intracellular messenger.

Paracrine communication The release of an extracellular signaling molecule by one cell in the local vicinity of the target cell that has the appropriate membrane receptors to respond to the signal. Diffusion carries the signal from the releasing cell to the target cell.

Photolysis The use of ultraviolet light to break chemical bonds. The molecule that absorbs the ultraviolet light is often called a 'caged compound' and has no biological action. The ultraviolet light cleaves the molecule into an active compound ('uncaged') and inactive remnant.

Introduction

Intercellular calcium (Ca^{2+}) waves consist of increases in cytoplasmic Ca^{2+} ion concentration ($[\text{Ca}^{2+}]_i$) that are communicated between cells and appear as waves that radially spread out from an initiating trigger cell. These Ca^{2+} waves propagate for variable periods (up to tens of seconds) with speeds of approximately $10\text{--}20\ \mu\text{m s}^{-1}$ and may involve tens to hundreds of contiguous cells. The actual speed and size of the Ca^{2+} wave depend on the nature and strength of the initiating stimulus and the mechanism of propagation. Ca^{2+} waves that only propagate within a single cell are called 'intracellular Ca^{2+} waves'.

The first major reports of intercellular Ca^{2+} waves were made in 1990 which described Ca^{2+} waves propagating either through cultures of astrocytes in response to extracellular glutamate or through airway epithelial cells following mechanical stimulation of a single cell. Subsequently, intercellular Ca^{2+} waves have been found to be initiated by a variety of stimuli in a wide range of cell types, including bone, pancreatic, epithelial, endothelial, and smooth muscle cells.

Intercellular Ca^{2+} waves are complex spatio-temporal events that involve active signal transduction within and between cells and are limited by passive physical characteristics of diffusion and cell architecture. As a result, our understanding of Ca^{2+} waves has arisen from investigations with real-time microscopy, molecular biology, and mathematical modeling. Interestingly, the use of mathematical models to understand inter- and intracellular Ca^{2+} waves has itself driven the development of two- and three-dimensional models that previously

only included a time domain (i.e., mechanisms of Ca^{2+} oscillations). From these studies, it is now recognized that there are three key parameters, namely the mechanisms of wave initiation, wave propagation, and messenger regeneration, which characterize the varying behavior of intercellular Ca^{2+} waves in different cell types.

Ca^{2+} Wave Initiation

The variety of stimuli that can trigger an intercellular Ca^{2+} wave ranges from a focal stimulus of a single cell to a global stimulation of a population of cells with selected agonists. Focal initiation is commonly achieved by mechanical stimulation of a cell with a micropipette. Alternatively, local stimulation may involve electrical stimulation with a microelectrode, the photoactivation of a Ca^{2+} ionophore to transiently increase plasma membrane Ca^{2+} permeability, the photolytic release of inositol 1,4,5-trisphosphate (IP_3) within a cell to elevate Ca^{2+} , or the extracellular iontophoresis of adenosine triphosphate (ATP) for partial P2 receptor activation. Global stimuli usually involve a uniform exposure of the cells to a neurotransmitter (i.e., glutamate) or to a reduced extracellular Ca^{2+} concentration. Mechanical stress may also be applied globally.

In general, stimuli that bring about a local increase in $[\text{Ca}^{2+}]_i$ are often wave-triggering events. However, in early work, it was found that mechanical stimulation in Ca^{2+} -free conditions initiated a propagating intercellular Ca^{2+} wave even though the stimulated cell did not display increases in $[\text{Ca}^{2+}]_i$. This response indicated that a Ca^{2+} increase within the

stimulated cell was not essential to trigger a Ca^{2+} wave and this led to the idea that an alternative messenger was involved. It is now well accepted that this alternative signal is the upstream second-messenger IP_3 ; this messenger serves as a powerful trigger of Ca^{2+} release from the endoplasmic reticulum (ER) and an instigator of many intra- and intercellular Ca^{2+} waves.

Ca^{2+} Wave Propagation

Intercellular Ca^{2+} wave propagation involves two steps: the propagation of the Ca^{2+} wave across a cell, followed by the transmission of the Ca^{2+} wave between cells. While both these processes involve the diffusion of messengers, they are mediated by different mechanisms.

Intracellular Propagation

The mechanism for the propagation of Ca^{2+} waves through cells is strongly dependent on the Ca^{2+} excitability of the cytosol (i.e., the ability with which a small, local transient elevation in $[\text{Ca}^{2+}]_i$ can be amplified into a large spreading Ca^{2+} pulse) and the diffusing messenger. To appreciate these mechanisms, the characteristics and spatial distribution of the Ca^{2+} release channels of the ER must be understood.

Ca^{2+} -permeable receptor/channels occur within the ER membrane of most cells in two forms: the IP_3 receptor (IP_3R) and the ryanodine receptor (RyR – named for its affinity for the plant alkaloid). The open probability of the IP_3R is primarily increased by the binding of IP_3 . Similarly, the open probability of the RyR is increased by the binding of Ca^{2+} . In addition, the RyR may also be sensitized by cyclic adenosine diphosphate-ribose (cADP-ribose). Importantly, the IP_3R and RyR are also functionally similar in that their Ca^{2+} permeability is also regulated via a process known as ' Ca^{2+} -induced Ca^{2+} release' (CICR). CICR is mediated by a positive-feedback mechanism in which the local increase in Ca^{2+} acts on the receptors to further increase their open probability and enhance Ca^{2+} efflux (Figure 1).

Although the IP_3R and RyR are believed to be distributed throughout the cell (in the ER), their distribution may not be uniform and it is believed that these channels are arranged in clusters, most likely, containing both IP_3R and RyR s.

The mechanism of intracellular Ca^{2+} wave propagation that was first experimentally described is based on the diffusion of IP_3 from a restricted stimulation site. This type of Ca^{2+} wave was hypothesized to be initiated by mechanical stimulation and is reproduced by a transient, localized iontophoretic or photolytic release of IP_3 . As expected, inhibition of IP_3Rs abolished these Ca^{2+} waves. Following liberation, IP_3 immediately diffuses in all directions. In doing so, it encounters, binds to, and activates IP_3Rs to release Ca^{2+} from the ER. As mentioned earlier, the IP_3R is also sensitive to Ca^{2+} . Consequently, a self-amplifying increase in $[\text{Ca}^{2+}]_i$, mediated by CICR via the IP_3R , follows the diffusive spread or wave of IP_3 (Figure 1).

Because Ca^{2+} also activates CICR via RyRs , it is likely that Ca^{2+} wave propagation can be enhanced by local increases and diffusion of Ca^{2+} , especially if the IP_3R and RyR are co-localized in receptor clusters. Under special circumstances, such as global agonist stimulation, where the IP_3 concentration is likely to be uniform throughout all cells or where the RyR has been sensitized with cADP-ribose, Ca^{2+} diffusion alone may propagate the Ca^{2+} wave. Thus, the rate of Ca^{2+} wave propagation is a complex function of IP_3 and Ca^{2+} diffusion, sequential CICR via sensitized IP_3Rs and RyRs , and the distribution and composition of these ion/receptor clusters (Figure 1).

Because CICR through the IP_3R and RyR is a self-limiting process, the $[\text{Ca}^{2+}]_i$ increase associated with a Ca^{2+} wave often has a similar amplitude at all locations across the cell. By contrast, the concentration of the underlying diffusive IP_3 wave is believed to decrease with distance from the initiation site (proportional to the inverse distance squared). Unfortunately, unlike the changes in $[\text{Ca}^{2+}]_i$, these changes in $[\text{IP}_3]_i$ cannot be as easily visualized by imaging techniques because of the limitations of reporter dyes for IP_3 . However, it is important to point out that as long as the $[\text{IP}_3]_i$ at the diffusive wave front remains greater than the threshold for activation of the

Figure 1 Basic mechanisms of a diffusive Ca^{2+} wave across a cell (either initiating or communicating). Inositol trisphosphate (IP_3) diffuses across the cell and binds to an IP_3 receptor (IP_3R) to stimulate Ca^{2+} release from the endoplasmic reticulum (ER). The positive feedback (+ve) of Ca^{2+} on the IP_3R initiates Ca^{2+} -induced Ca^{2+} release (CICR) through the IP_3R . The elevated Ca^{2+} has a negative feedback (–ve) on the IP_3R to terminate CICR and limit the Ca^{2+} increase. Some Ca^{2+} may diffuse to adjacent ryanodine receptors (RyR) to initiate CICR via these receptors. However, IP_3 diffusion occurs more quickly than Ca^{2+} diffusion (due to cytosol protein buffers) and propagates the Ca^{2+} wave. IP_3 may have been produced in response to cell stimulation or by entering the cell via a gap junction.

IP_3 ($\sim 10\text{--}30\text{ nM}$), Ca^{2+} release will continue to be initiated and a Ca^{2+} wave will appear to propagate without a degradation. In large cells, such as oocytes (diameter $>200\text{ }\mu\text{m}$), the Ca^{2+} waves have a trailing edge of decreasing $[\text{Ca}^{2+}]_i$ which represents the return of the Ca^{2+} to the ER by the action of sarcoplasmic/endoplasmic reticulum Ca^{2+} (SERCA) pumps (Figure 1). However, in small cells (diameter $10\text{--}20\text{ }\mu\text{m}$), Ca^{2+} waves often do not have a trailing edge because the Ca^{2+} release dynamics persist for periods that are longer than the time taken for the Ca^{2+} waves to travel across the cell.

Intercellular Propagation

At the cell border, the cell membrane limits both IP_3 and Ca^{2+} diffusion and hence CICR. Consequently, the transmission of the Ca^{2+} wave to the next cell must occur by a modified or alternative mechanism. There are two major scenarios for this process. The first mechanism, originally characterized, occurs by cell-cell communication via gap junctions (GJs). The second mechanism, subsequently discovered, occurs by paracrine signaling with an extracellular messenger (Figure 2).

GJ communication

GJs are large arrays of transmembrane channels that connect the cytoplasm of two cells and thereby provide a direct diffusion pathway between cells. Cells sharing a GJ each provide a hemi-channel (or connexon) that interact to form the complete GJ channel. Each hemi-channel is composed of proteins called connexins of which there are more than 20 different isoforms (i.e., Cx 23 to 62). By labeling connexin-43 with green fluorescent protein (GFP) to localize GJs, it has been demonstrated that Ca^{2+} waves in transfected HeLa cells propagated across cell borders exactly at the site of the GJ. The types of isoforms forming each GJ determine the properties of the GJ

Figure 2 Overall hypothesis for the communication of intercellular Ca^{2+} waves: local stimulation can lead to elevated IP_3 in the initiator cell. As IP_3 diffuses across this cell, it generates an intracellular Ca^{2+} wave by the release of Ca^{2+} through IP_3Rs with amplification from RyRs . Diffusion of IP_3 through a gap junction to an adjacent cell initiates a second intracellular Ca^{2+} wave, via IP_3Rs and RyRs . In addition, or alternatively, the stimulated cell releases ATP (in either a Ca^{2+} -dependent or -independent manner) via hemi-channels in the plasma membrane. The extracellular diffusion of ATP (or similar messenger) to adjacent cells activates P2 receptors which, in turn, stimulate IP_3 production to generate a Ca^{2+} signal in the adjacent cell. Propagation occurs by the regenerative release of ATP. Each mechanism can occur in isolation or synergistically.

and the maximum permeability of a GJ channel, in terms of molecular weight (MW), is approximately $1\text{--}1.5\text{ kDa}$. This has the implication that GJs are readily permeable to Ca^{2+} ions ($\text{AW} = 40$) and IP_3 (MW 486).

Although both IP_3 and Ca^{2+} have the ability to diffuse to adjacent cells via GJs, the relative importance of each messenger in the propagation of intercellular Ca^{2+} waves varies with circumstances. Because Ca^{2+} , but not IP_3 , is strongly buffered by cytoplasmic proteins, Ca^{2+} movement within a cell is much slower than that of IP_3 (effective diffusion coefficients of ~ 13 and $\sim 280\text{ }\mu\text{m}^2\text{ s}^{-1}$, respectively). In addition, the number of moles of Ca^{2+} required to spread over a similar distance is much greater than for IP_3 due to Ca^{2+} attrition associated with the buffers. This implies that after permeation of the GJ, IP_3 is more likely to reach an IP_3R in the connected cell than Ca^{2+} . Because IP_3 stimulates the release of Ca^{2+} from IP_3Rs , IP_3 diffusion can reignite CICR in the adjacent cell to drive the propagation of a second intracellular Ca^{2+} wave (Figure 2). If the diffusion distance from GJ channel to the first cluster of $\text{IP}_3\text{R/RyRs}$ is small, the difference in diffusion time for Ca^{2+} and IP_3 will be less and Ca^{2+} ions by themselves may trigger an intracellular Ca^{2+} wave in the connected cell. This is likely to be the case in the presence of a global agonist and a uniform distribution of IP_3 . The possibility that Ca^{2+} can serve as the primary messenger is also enhanced by increased GJ coupling. This allows greater amounts of Ca^{2+} to reach the adjacent cell, which is necessary to overcome the buffering capacity of the cytoplasm, in order that Ca^{2+} can reach an ER receptor. Examples of this type of communication have been reported in pancreatic acinar cells, hepatocytes, and blowfly salivary gland cells. A combination of the two diffusive processes may also occur in which IP_3 initially arrives at receptor clusters, but at concentrations too low to trigger significant Ca^{2+} release. However, this IP_3 concentration is sufficient to sensitize the IP_3Rs to the following Ca^{2+} that can initiate CICR. These various transmission modes have been reported to occur in different cell types.

A frequently observed characteristic of intercellular Ca^{2+} wave propagation via GJs is a delay ($\sim 0.5\text{--}1\text{ s}$) between the Ca^{2+} wave reaching the cell membrane and the continuation of the wave in the adjacent cell. This delay is believed to represent the diffusion time for IP_3 and/or Ca^{2+} from one cell to the next. Mathematical modeling of wave propagation predicts that there is a minimal GJ permeability required to allow wave transmission between cells and that the GJ permeability required for the propagation of Ca^{2+} waves is inversely related to the effective diffusion constant of the propagating messenger and the Ca^{2+} excitability of the cytosol.

In addition to the diffusion of IP_3 or Ca^{2+} between cells, cADP ribose (MW 541 Da), which can also sensitize RyRs to Ca^{2+} , may mediate GJ-propagated Ca^{2+} waves in lens cells and astrocytes. However, these intercellular Ca^{2+} waves have slower kinetics and propagate smaller distances as compared to Ca^{2+} waves propagated by IP_3 diffusion. This might be expected for waves relying on Ca^{2+} diffusion.

Paracrine communication

Ca^{2+} waves may also be propagated by paracrine signaling between adjacent cells. In this process, a second messenger, released by one cell, diffuses across the extracellular space between cells. After binding to membrane receptors on neighbor

cells, the messenger triggers a Ca^{2+} elevation. Early evidence for this mechanism came from the ability of intercellular Ca^{2+} waves to propagate across a cell-free zone and by the biasing of the propagation direction by an extracellular fluid flow. It has now been demonstrated that the primary extracellular messenger is ATP in many cell types, including hepatocytes, keratinocytes, mast cells, bone cells, and various types of epithelial, endothelial, and glial cells (Figure 2). Indeed, with advanced imaging techniques using bioluminescent probes to detect ATP, intercellular Ca^{2+} waves have been observed to be associated with a cloud of extracellular ATP.

While ATP can activate ionotropic (ligand-gated ion channels, i.e., P2X family) and metabotropic receptors (i.e., P2Y family), Ca^{2+} waves appear to arise most commonly from metabotropic stimulation. This involves the activation of G-protein-coupled receptors, stimulation of phospholipase C, and the generation of IP_3 followed by Ca^{2+} release from the ER via the IP_3R (Figure 2). However, extracellular ATP is prone to rapid degradation by ectonucleotidases with sub-second kinetics, and the resulting metabolites adenosine diphosphate (ADP), adenosine monophosphate (AMP), and adenosine may also contribute to Ca^{2+} wave propagation. The consequence of this scenario is that the characteristics of paracrine Ca^{2+} wave propagation is a complex function of the rates of ATP and metabolite release, the spectrum of the purinergic metabotropic receptors present, and the varying affinities of ATP and its metabolites for these receptors (e.g., ADP is more potent than ATP on P2Y1 receptors).

After the initial reports that intercellular Ca^{2+} waves involved both GJs and extracellular ATP, it was quickly discovered, with the use of transgenic animals and gene silencing techniques, that ATP release was connexin dependent. In order to form GJs, connexins normally associate into hexameric assemblies in the plasma membrane called 'hemi-channels'. However, a fraction of these hemi-channels do not pair up to form the GJ and remain in the membrane. These connexin hemi-channels are normally closed but can open in response to a variety of stimuli, including changes in membrane voltage, phosphorylation, redox state, $[\text{Ca}^{2+}]_i$, metabolism, and hypoxia/ischemia, thereby bringing about ATP release (Figure 2). A similar effect may occur through hemi-channels composed of pannexins, proteins that are structurally similar to connexins but without sequence homology. Because pannexin hemi-channels are externally glycosylated and less likely to form GJs, these channels might be more likely to be involved in ATP release. Pannexin-1 hemi-channels also contribute to the large conductance pore recruited upon long-term exposure of P2X₇ receptors to ATP. P2X₇ receptors are thus equipped with both an ATP-receptor and an ATP-release mechanism.

In addition to this transient flow of ATP through an open channel or pore (diffusive release), it appears that ATP in other non-neuronal cells occurs as discrete packets associated with vesicle fusion with the membrane (vesicular release). However, the vesicles storing ATP do not appear to belong to the classical clear (glutamatergic) or dense-core (noradrenergic) vesicles, but may involve organelles such as lysosomes.

Although ATP appears to be the most common paracrine messenger, some intercellular Ca^{2+} waves are communicated by the release of glutamate and nitric oxide, while others rely on changes in external Ca^{2+} ion concentration. During the

recovery from a cytoplasmic Ca^{2+} transient, Ca^{2+} is pumped both back into the ER by SERCA pumps and out of the cell by plasma membrane Ca^{2+} (PMCA) pumps. Because of the small spaces between cells, this can result in a localized elevation of the extracellular (or interstitial) $[\text{Ca}^{2+}]$ that can stimulate Ca^{2+} -receptors of neighbor cells, thereby triggering phospholipase C (PLC) activation, IP_3 formation, and a Ca^{2+} wave.

Spatial characteristics of GJ and paracrine Ca^{2+} waves

In addition to the observation that GJ-based Ca^{2+} waves typically experience a delay in propagating from one cell to the next, these Ca^{2+} waves frequently follow a convoluted pathway through multiple cells because of heterogeneities in the degree and spatial distribution of cell-cell coupling. By contrast, paracrine-based Ca^{2+} waves propagate in a more direct or homogeneous manner (circular wave front), but may be influenced by heterogeneities in plasma membrane receptor densities. It is not uncommon for individual cells, probably because of a lack of appropriate receptors, to be bypassed and not exhibit a Ca^{2+} wave, a behavior reiterating the ability of paracrine-based Ca^{2+} waves to communicate across cell-free zones.

These different behaviors are also reflected at the subcellular level. In GJ-based Ca^{2+} waves, the intracellular Ca^{2+} waves initiated in the receiving cell always start from a site of cell membrane contact with the donor cell; this represents the location of the GJs and the point of entry of the diffusible messenger (IP_3 , Ca^{2+} , etc). In paracrine-based Ca^{2+} waves, the Ca^{2+} signals in the receiving cell can occur anywhere within the cell because of the random location of the receptor and the subsequent process of signal transduction; frequently, Ca^{2+} signals were first observed in the vicinity of the peri-nuclear ER. Interestingly, despite these differences in propagation pathways, the propagation velocity of GJ- or paracrine-based Ca^{2+} waves is approximately similar and in the range of 10–20 $\mu\text{m s}^{-1}$. This is presumably because the MWs (486, 507, and 292 Da, respectively), and, therefore, the diffusion constants, of IP_3 , ATP, and glutamate are approximately similar.

For clarity, we have addressed the propagation mechanisms of GJ- and paracrine-based Ca^{2+} separately. However, it is important to emphasize, that in many cells, these two mechanisms are active simultaneously and synergistic. Thus, a propagating Ca^{2+} wave can be driven by IP_3 diffusing via GJs, while ATP is released via Ca^{2+} -dependent or -independent mechanisms. Ca^{2+} waves that rely exclusively on IP_3 diffusion via GJs propagate only limited distances, generally up to five cells, although this depends on the amount of IP_3 generated and the degree of GJ coupling. Paracrine Ca^{2+} waves propagate for much greater distances, mainly because they also have a regenerative process regulating the release of ATP (Figure 2).

Passive and Active Waves

Intercellular Ca^{2+} waves that rely on the diffusion of IP_3 via GJs or extracellular ATP from a single initiator cell are sometimes termed 'diffusive Ca^{2+} waves'. They involve a decreasing concentration gradient of messenger from the stimulation point that provokes Ca^{2+} increases (and wave propagation) as long

as the messenger concentration (in either the intra- or extracellular space) is above a threshold level for receptor stimulation. Diffusive Ca^{2+} waves are essentially passive Ca^{2+} waves and analogous to the electrotonic spread of changes in membrane potential between cells. When passive waves are enhanced by messenger (intra- or extracellular) regeneration, the wave propagation becomes active. In principle, pure active waves should never stop propagating. However, in reality, Ca^{2+} waves often rely on a combination of passive and active mechanisms and even active Ca^{2+} waves terminate.

Messenger Regeneration in Active Intercellular Ca^{2+} Waves

Internal Messengers

Because phospholipase C_δ (PLC_δ) is Ca^{2+} dependent, its activation has been implicated in GJ-based Ca^{2+} waves. The influx of IP_3 triggers a Ca^{2+} increase that, in turn, activates further IP_3 synthesis to enhance Ca^{2+} wave velocity and propagation distance by maintaining a sustained and increased $[\text{IP}_3]$ difference between adjacent coupled cells. The extent of the contribution of IP_3 regeneration by PLC_δ is not well defined but inclusion of a limited regenerative process in mathematical models of Ca^{2+} waves often improves the fit to experimental data.

External Messengers

An early observation of paracrine-based Ca^{2+} waves that cross cell-free zones was that the distance between the initiation site and the border of the cell-free zone was not critical for wave propagation on the distal side of the cell-free area. This implied that the concentration of the extracellular messenger at the cell border was dependent on messenger release by cells near the border. In addition to Ca^{2+} -dependent release of ATP or glutamate, as previously discussed, a Ca^{2+} -independent ATP-induced ATP release occurs in astrocytes. It is proposed that ATP binding to P2X_4 or P2X_7 receptors results in the opening of large associated pores that allows diffusive ATP release. This would be expected to result in faster and more extensive Ca^{2+} waves, and mathematical models that include Ca^{2+} -dependent and -independent extracellular messenger confirm this prediction.

Within a uniform cell layer, extracellular messenger regeneration across cells might be expected to generate a homogeneous wave front. However, using luciferase-based luminometry, it was demonstrated that only specific cells within the Ca^{2+} wave (identified by the uptake of connexin hemi-channel-permeable fluorescent dyes) generated a burst of ATP. This behavior suggests that intercellular Ca^{2+} waves may propagate in a saltatory manner; that is, the waves jump between trigger cells, perhaps because only a certain population of cells have the necessary receptors to take part.

An important additional point is that extra/intracellular messenger regeneration is often counterbalanced by degradation and this can limit or slow propagation. For ATP, rapid degradation occurs via ectonucleotidases to various adenosine analogs. For IP_3 , the active concentration can be reduced by de-phosphorylation to IP_2 by a 5-phosphatase or by phosphorylation to IP_4 by a 3-kinase.

Phase Waves

A unique form of Ca^{2+} signaling, which has been characterized in hepatocytes, appears as an intercellular Ca^{2+} wave, but is, in fact, a phase wave – an ordered but independent temporal sequence of Ca^{2+} events. If a row of cells is exposed to conditions that generate a progressive decrease in $[\text{IP}_3]_i$ in each cell, it is possible to get the impression of a cell-to-cell propagating wave because each cell shows a Ca^{2+} spike with a slight delay with respect to the neighboring cells. Radial rows of hepatocytes have a gradient of plasma membrane G-protein-coupled receptors responsive to the hormones noradrenalin or vasopressin. Uniform exposure to these agonists establishes an $[\text{IP}_3]_i$ gradient within the cells. However, this gradient can be modulated by GJ communication. Ca^{2+} phase waves have been observed both *in vitro* and *in vivo* with intact perfused liver preparations.

Intercellular Ca^{2+} Waves in Isolated Tissues and *In Vivo*

Because most of our knowledge of intercellular Ca^{2+} waves is derived from *in vitro* monolayers of cultured cells, it is important to ask if such Ca^{2+} waves exist *in vivo* and what is their function? Similarly, it is important to consider if the stimuli used to evoke waves *in vitro* are relevant (in both strength and form) to *in vivo* conditions.

Intercellular Ca^{2+} waves have been demonstrated in glial cells, more specifically astrocytes and Müller cells in acutely isolated rat retina in response to local mechanical stimulation. Similarly, large intercellular Ca^{2+} waves, in response to mechanical stimulation, have been found in radial glial cells in the neocortex in partial brain preparations from embryonic rats. In mouse cortical brain slices, step increases in Ca^{2+} induced by photolysis of caged Ca^{2+} and electrical stimulation induced intercellular Ca^{2+} waves that propagated for distances greater than 100 μm . Ca^{2+} waves in neocortex slice preparations were found to be dependent on GJs, based on their sensitivity to the GJ blocker carbenoxolone or conditional knockout of connexin 43 expression in astrocytes. By contrast, intercellular Ca^{2+} waves triggered by electrical stimulation in the CA1 region of hippocampal slices are unaffected by carbenoxolone but significantly reduced by suramin, a blocker of P2 receptors, results indicating a paracrine-purinergeric communication. It is also important to emphasize that the properties of intercellular Ca^{2+} waves in nervous tissues and brain slices are influenced by neuronal involvement. When the neuronal contribution is abolished by low extracellular Ca^{2+} conditions (inhibition of presynaptic Ca^{2+} entry) or tetrodotoxin (blockage of voltage-sensitive sodium channels), the propagation speed of and distance traveled by Ca^{2+} waves are comparable to that observed in pure astrocyte cultures. With the neuronal network active, Ca^{2+} waves propagate faster and further, presumably as a result of glutamate leakage from synapses acting to influence the astrocytes. *In vivo* recordings in the brain of anesthetized rodents with two-photon microscopy have revealed spontaneous Ca^{2+} changes in cortical astrocytes, with some degree of coordinated wave-like organization of the signal. Increasing brain activity induced with bicucullin, which induces seizures, in turn, increases the coordination and

wave-like behavior. From these examples, it appears that intercellular Ca^{2+} waves *in vivo* are smaller as compared to those *in vitro*, irrespective of the preparation. One reason for this is the fact that *in vivo* conditions are three-dimensional and thereby contribute to reduced diffusion distance for the intra- or extracellular messengers and increased metabolism of the messenger. In addition, an intact vasculature will also facilitate the clearance of the extracellular messenger from the interstitial space. If messenger clearance is faster than the latency associated with Ca^{2+} signal induction and subsequent intracellular Ca^{2+} wave generation, the intercellular wave propagation will be limited. Despite the fact that intercellular Ca^{2+} waves can be triggered by exogenous stimulation, there is currently little evidence supporting the presence of such waves during normal brain activity. Recent work indicates that intercellular Ca^{2+} waves may occur spontaneously in the hypothalamus and cerebellum, and in the vicinity of amyloid plaques in animal models of Alzheimer's disease.

Other *in vivo* data on intercellular Ca^{2+} waves are available from isolated and blood-perfused lung preparations. Photolysis of caged Ca^{2+} in a single endothelial cell of alveolar capillaries has been reported to trigger Ca^{2+} changes up to 150 μm away from the stimulation site and to propagate from capillaries to venous blood vessels. Spatially propagating Ca^{2+} changes were absent in mouse lungs lacking connexin 43 and inhibited by peptide blockers of GJs. A consequence of the endothelial propagating Ca^{2+} wave was an increase in the P-selectin expression and potentiation of thrombin-induced microvascular permeability.

The final major question is what is the major function of intercellular Ca^{2+} waves? This still remains difficult to answer, but the ubiquitous nature of Ca^{2+} waves in diverse tissues with alternative mechanisms of action underscores the idea that they are important. The least attractive idea would be that Ca^{2+} waves, while exploiting inherent cell Ca^{2+} signaling mechanisms, are simply an excessive response to experimental stimulation. By contrast, activities known to be stimulated by Ca^{2+} increases, such as vesicle secretion, would be expected to be enhanced by a Ca^{2+} wave. This might be the case in blowfly salivary glands following local neural stimuli to salivate. However, a strong correlation between cell activity and Ca^{2+} waves has only been reported for airway epithelial cells. The passage of a Ca^{2+} wave initiated an increase in ciliary activity in adjacent cells. Because cilia are more effective when beating in coordinated groups, this example readily supports the idea that Ca^{2+} waves serve to coordinate tissue, rather than cell, responses. These ideas are supported by data pointing to a role of Ca^{2+} waves in coordinating the metabolic activity of glial cells and also apply for the communication between different cell types such as endothelial–glial cells at the blood–brain barrier, glial–neuron interactions in the brain, or endothelial–smooth cells in the vasculature. An alternative idea, in view of the fact that mechanical stimuli often initiate prominent Ca^{2+} waves, is that

this is a response to local injury, with the propagating waves serving to stimulate the cells near the injury site to initiate a healing process. The Ca^{2+} waves would provide a direction clue as the injury site. Other intriguing possibilities are that Ca^{2+} waves are associated with spreading depression of neural activity in the brain or the infarcts associated with ischemic events.

In conclusion, intercellular Ca^{2+} waves form a common dynamic signaling event expressed by diverse cell types in response to a variety of stimuli. Moreover, the multiple mechanisms used to propagate intercellular Ca^{2+} waves that exploit specific signaling and structural architectures of different cells suggest an essential redundancy that is common to vital activities. Consequently, Ca^{2+} waves are likely to be important in coordinating cell functions in multicellular tissues, an idea that will be explored by our increasing desire and ability to understand intact systems.

Glossary

Cytokine receptor A cell-surface protein that binds to a distinct extracellular polypeptide hormone and induces a response within the cell.

Interferon Cytokines involved in regulating antiviral and immune responses.

Kinase An enzyme that phosphorylates (adds a phosphate group to) a protein.

Signal transduction The conversion of an extracellular signal to an intracellular response.

Transphosphorylation The reaction by which one protein causes the addition of a phosphate group to another protein.

Interferons (IFNs) are a family of cytokines, or protein hormones, which modulate the immune response and provide resistance to viral infection. The effects of IFN are mediated through cell-surface receptors, which recognize extracellular IFN and activate cellular signaling pathways, ultimately leading to gene induction and repression. IFNs are divided into two classes, type-I and type-II IFNs. There are multiple members of the type-I IFN family, including IFN- α and IFN- β , whereas IFN- γ is the only known type-II IFN. The two types of IFNs bind to two distinct receptors and have very different cellular outcomes. Type-I IFN receptors predominantly activate an antiviral, innate immune response. Signaling through type-II IFN receptors, on the other hand, is involved in modulating the adaptive immune response. Both types of receptors share, in common, the ability to, directly and quickly, induce new gene transcription through the activation of JAK/STAT signaling pathways.

IFN receptors are classified as type-II cytokine receptors. Both type-I and type-II cytokine receptors have extracellular and intracellular domains connected by a single transmembrane domain. The extracellular domains of cytokine receptors contain a conserved tandem fibronectin type-III (FNIII) motif, which is distinguished by unique cystine pairings at both ends of the domain. Type-II cytokine receptors lack an additional conserved Trp-Ser-X-Trp-Ser motif, found in the extracellular domain of type-I receptors. Ligand binding to the receptor leads to receptor oligomerization and activation of a signaling cascade. In addition to type-I and type-II IFN receptors, the receptors for tissue factor and the cytokine IL-10 belong to this class. The IFN receptors and the IL-10 receptor are composed of two different subunits, both of which are required for proper functioning of the receptors.

IFN- γ Receptors

Expression of IFN- γ and Its Receptor

Expression of the IFN- γ receptor is common to almost all cell types with the exception of mature red blood cells. Two genes, IFN- γ R1 and IFN- γ R2, encode the receptor components.

The human IFN- γ R1 gene is located on the long arm of chromosome 6. The expression of IFN- γ R1 messenger RNA

(mRNA) is not regulated by any known stimuli, but appears to be under standard housekeeping controls. Although the IFN- γ receptor functions on the cell surface, a large intracellular reserve of IFN- γ R1 is present in some cells at levels up to 2–4 times the amount of receptor present on the cell surface. This reserve serves to keep the surface level of IFN- γ R1 constant.

The human gene for IFN- γ R2 is located on chromosome 21. The mouse gene for IFN- γ R2 is on chromosome 16. Study of the mouse gene promoter has revealed that it contains binding sites for a number of activated transcription factors, suggesting that unlike IFN- γ R1, IFN- γ R2 expression can be regulated. Both proteins must be expressed on the cell surface and associate in order for IFN- γ signaling to occur, but there is evidence that some T cells control their responsiveness to IFN- γ by modulating the cell-surface expression of IFN- γ R2.

Unlike the receptors, IFN- γ is expressed only in response to stimulus by antigen and only in cells of lymphoid origin, in particular, natural killer cells, macrophages, and some T cells. Once synthesized, IFN- γ is secreted and signals as a homodimer.

Receptor Structure

Both IFN- γ R1 and IFN- γ R2 have extracellular and intracellular domains, along with a single transmembrane domain, common to all type-II cytokine receptors. The sequences of extracellular domains can vary greatly among species causing highly species-specific IFN- γ binding. By contrast, intracellular domains of the IFN- γ receptor subunits are more conserved among species, and can be substituted freely. The intracellular domains mainly serve as a scaffolding structure for the interaction of downstream-signaling proteins and contain no enzymatic activity of their own. The IFN- γ R1 is a 90-kDa glycoprotein consisting of 472 amino acid residues. The first 228 residues of the protein comprise the extracellular domain. IFN- γ R1 has a 24-amino-acid transmembrane domain and an intracellular domain that spans the C terminus from residues 252 to 472. IFN- γ R2 is a 62-kDa, 315-amino-acid residue protein. Both the extracellular and transmembrane domains of IFN- γ R2 are comparable in length to those of IFN- γ R1. Residues 1–226 form the extracellular domain and 227–250 are the transmembrane domain. At only 65 amino

acid residues, the intracellular domain of IFN- γ R2 is much smaller than that of IFN- γ R1.

The crystal structure of a soluble, truncated version of the extracellular domain of human IFN- γ R1 is known. It contains two distinct domains, both consisting of two β -sheets and displaying fibrillin-3 topology. An 11-amino-acid linker connects the two domains. The binding of ligand is accomplished through the interaction of both domains.

Ligand Binding

IFN- γ binds to the extracellular domain of IFN- γ R1 only. In the absence of IFN- γ R1, IFN- γ R2 cannot bind IFN- γ . However, the presence of IFN- γ R2 does strengthen the association of IFN- γ and IFN- γ R1 threefold, though the two subunits of the receptor do not associate in the absence of IFN- γ . Further, IFN- γ R2 is vital for IFN- γ signal transduction, and for this a highly specific interaction must occur between the extracellular domains of IFN- γ R1 and IFN- γ R2.

An active signaling complex consists of an IFN- γ homodimer and two chains each of IFN- γ R1 and IFN- γ R2. Each subunit of the IFN- γ homodimer binds an IFN- γ R1 chain, which in turn binds IFN- γ R2. In the absence of IFN- γ R2, IFN- γ R1 molecules bound to an IFN- γ homodimer are separated by over 27 Å and, therefore, are unable to interact with each other.

Signal Transduction

Janus tyrosine kinase (Jak)/signal transducer and activator of transcription (STAT) signaling is carried out through a series of tyrosine phosphorylation events, at the receptor, mediated by members of the Jak family. Signaling culminates with the activation and nuclear translocation of STAT proteins, where they function to induce new mRNA synthesis. The IFN receptors serve as docking sites for both Jak1 and Jak2. With the formation of IFN-receptor complex, Jak proteins are brought into close proximity, which enables them to transphosphorylate and thereby activate each other. Independent of IFN binding to the extracellular domain of the receptor, the Jak proteins, Jak1 and Jak2, associate with the intracellular domains of IFN- γ R1 and IFN- γ R2, respectively (Figure 1(a)). Upon the formation of a receptor complex with IFN- γ , Jak2 transphosphorylates Jak1 (Figure 1(b)). Jak1 then transphosphorylates Jak2, and either Jak phosphorylates IFN- γ R1 at Tyr440 (Figure 1(c)). Phosphorylation of IFN- γ R1 in turn leads to the recruitment and binding of a STAT1 protein to each IFN- γ R1 chain. The bound STAT1 proteins are phosphorylated by the Jaks, and they disassociate from the receptor and form a homodimer (Figure 1(d)). This complex then translocates to the nucleus where it can induce the transcription of many genes.

STAT-dependent signaling is the best-studied IFN- γ signaling pathway, but there is evidence that STAT1-independent

Figure 1 Kinetics of the IFN- γ signaling cascade (a–d), showing the proteins and tyrosine phosphorylation events involved in signal transduction by the IFN- γ receptor.

signaling pathways can also be activated by IFN- γ through IFN- γ R1 and IFN- γ R2. In cell lines lacking STAT1, activation of the IFN- γ receptor by IFN still causes the induction of a set of genes.

In order for signal transduction to occur normally, two regions of the intracellular domain of IFN- γ R1 and one region of the intracellular domain of IFN- γ R2 are required. The association of Jak1 with IFN- γ R1 requires the amino acid residues from 266 to 269, LPKS, located in the membrane proximal region. Distal to the membrane at amino acids 440–444, YDKPH comprise the STAT1-binding site. Within the intracellular domain of IFN- γ R2, a proline-rich 12-amino-acid sequence P²⁶³PSIPLQIEEYL²⁷⁴ is needed for Jak2 binding. Disruption of any of these three regions abolishes normal signaling.

Upon the binding of IFN- γ , the receptor complex is internalized. Internalized receptor–ligand complex is trafficked to an acidic compartment. IFN- γ disassociates from the receptor, goes to the lysosome, and is degraded, whereas the IFN- γ R1 subunit of the receptor is recycled into the cytoplasmic reserve. Mutation of either Leu 270 or Ile 271 inhibits the internalization of the receptor, leading to the accumulation of IFN- γ ligand–receptor complexes on the surface of the cell.

Effects of Signaling through the IFN- γ Receptor

IFN- γ can be thought of as the antimicrobial interferon. Signaling through type-II IFN receptors has pro-inflammatory effects and antibacterial effects. Mice lacking type-II IFN receptors have a much higher susceptibility to infection by bacteria and intracellular microbes. The antibacterial effects of IFN- γ are mediated through multiple pathways. IFN- γ leads to the activation of neutrophils, natural killer cells, and, in particular, macrophages, by increasing their ability to recognize, kill, and digest foreign material or microbes. In T cells, IFN- γ promotes the maturation of cytotoxic CD8 + T cells, as well as the T_H1 subset of CD4 + T cells. IFN- γ also enhances the humoral immune response by upregulating genes such as class-I and class-II major histocompatibility complex (MHC) molecules, along with cell-surface adhesion molecules. Together, these effects serve to augment the adaptive immune response to pathogens.

As would be expected, loss of the IFN- γ receptor genes leads to increased susceptibility to infection by microbes. Mice lacking the IFN- γ receptor genes are affected much more severely by infections with lysteria and mycobacteria. Otherwise, the receptor knockout mice display no developmental defects, have normal T cell responses, and are no more susceptible to most viral infections than wild-type mice. These effects are seen in humans as well. Children susceptible to infections with weakly pathogenic mycobacteria species, such as *M. avium*, were found to have mutations in the IFN- γ receptor genes. The susceptibility was mycobacteria specific, as these children did not have increased difficulties fighting off infections from other bacteria, viruses, or fungi.

An unexpected consequence of IFN- γ receptor loss is an increased susceptibility to tumor development. IFN- γ receptor knockout mice develop tumors at a much higher frequency than their IFN- γ responsive counterparts do. Compared to IFN- γ responsive tumors, IFN- γ unresponsive tumors are less prone to rejection when transplanted into immunocompetent wild-type

mice. Studies of human carcinomas have revealed that loss of responsiveness to IFN- γ is not uncommon. Taken together, these facts suggest that loss of IFN- γ signaling enables tumors to evade the normal surveillance mechanisms of the immune system. Normal expression of the IFN- γ receptor proteins is therefore important in preventing the development of cancer.

The IFN- α/β Receptor

Expression of IFN- α/β and Their Receptor

Like the IFN- γ receptor, the IFN- α/β receptor is composed of two polypeptides encoded by two genes. Both IFN- α/β receptor genes, IFN- α R1 and IFN- α R2, are clustered on human chromosome 21 (or chromosome 16 in mice) with IFN- γ R2 and IL-10R2 (also a member of the class-II cytokine family). Expression of the receptor proteins is thought to be ubiquitous, but it can also be modulated.

The gene encoding IFN- α R1 is 32 kb and contains 11 exons. The second through ninth exons encode the extracellular domain of the protein, while the last two exons encode the transmembrane and intracellular domains.

In the case of IFN- α R2, there are three splice variants of the protein encoded by a nine-exon gene. The 515 aa, IFN- α R2c, encoded by a 4.5-kb mRNA, is the only functional splice variant and has an extended intracellular domain compared to the other two variants. IFN- α R2b has a shorter cytoplasmic domain and cannot signal through the Jak–STAT pathway, and IFN- α R2a is a secreted form of the extracellular domain of the receptor only. Studies in mice, which express only homologs of the 2a and 2c splice variants, have shown that the 2a variant is expressed in greater abundance in most tissues, except in those of lymphoid origin where the two isoforms are expressed in a 1:1 ratio. It is not clear if the truncated splice variants play a functional role in modulating responsiveness to IFN; however, IFN- α R2a can act as a dominant-negative inhibitor for type-I IFN signaling.

There are many members of the type-I IFN family. The most well known among them are IFN- α and IFN- β , which share little structural homology with each other. IFN- β was first isolated from fibroblasts, while IFN- α was discovered in lymphoid cells. Within the IFN- α family alone, there are over 13 subtypes encoded by different genes. The proteins they synthesize can vary in size from 15 to 21 kDa, and contain different degrees of posttranslational modification. Despite the apparent diversity in type-I IFNs, they all bind to the same receptor composed of IFN- α R1 and IFN- α R2c. There is, however, variation in the type and degree of response generated.

Receptor Structure

The extracellular domain of IFN- α R1 spans the first 409 aa residues of the protein, and the intracellular domain contains the final 100 residues from amino acid 431 to 530. IFN- α R1 is unique among class-II cytokine receptors in that its extracellular domain contains four tandem FNIII domains, compared to the two contained by other IFN receptor proteins. When compared to IFN- α R1, the 217-amino-acid extracellular domain of IFN- α R2 is relatively short. By contrast, the intracellular

domain of IFN- α R2c is much longer than that of IFN- α R1, covering the C-terminal 251 amino acids. There is not nearly as much known about the structure of IFN- α/β receptors as that of IFN- γ receptors.

Ligand Binding

Both IFN- α R1 and IFN- α R2c bind type-I IFNs, cooperatively. This is different from the IFN- γ receptor where only IFN- γ R1 had ligand-binding activity. In addition, the signaling complex for the α/β -receptor consists of a single pair of receptor proteins as opposed to the two pairs that compose the γ -receptor complex.

Another feature of the IFN- α/β receptors is their ability to bind multiple ligands. Unlike IFN- γ receptors, which only bind

IFN- γ , the α/β -receptors can bind all subspecies of IFN- α , along with IFN- β and other type-I IFN species. Ligand-receptor interactions for the different classes of IFN are unique. By mutating residues in the extracellular portion of either receptor protein, it is possible to generate mutants, which bind and respond to IFN- β , but not all IFN- α species. The exact structural mechanism for how the differences in ligand binding translate into differences in downstream signaling effects is still unknown.

Signal Transduction

Signaling again occurs principally through the Jak-STAT pathway, but involves different members of the two families of proteins. Independent of ligand binding, Tyk2 a member

Figure 2 Signal transduction through the IFN- α/β receptor, showing the protein-protein associations and tyrosine phosphorylation steps involved. Numbers indicate the order in which tyrosine phosphorylation events (P) occur.

of the Jak family associates with IFN- α R1, while Jak1, STAT1, and STAT2 associate with IFN- α R2c (**Figure 2(a)**). The binding of ligand brings both receptor subunits into close proximity with each other. This allows Jak1 to transphosphorylate Tyk2 (**Figure 2(b)**). Tyk2 in turn phosphorylates Jak1 along with Tyr466 of IFN- α R1. The phosphorylation of Tyr466 of IFN- α R1 allows STAT2 to bind to it instead of IFN- α R2c. The IFN- α R1-bound STAT2 is phosphorylated on Tyr690 (**Figure 2(c)**). This leads to the STAT2-dependent phosphorylation of STAT1 on Tyr701. STAT1 and STAT2 dissociate from the receptor and form a heterodimer. The STAT1–STAT2 dimer associates with p48, or IRF9, a member of the interferon regulatory factor family, to form the transcription complex interferon-stimulated gene factor 3 (ISGF3). ISGF3 translocates to the nucleus, binds to interferon-stimulated regulatory element (ISRE) sequences present in the promoters of IFN-stimulated genes (ISGs) and induces transcription.

The binding sites for Jak and STAT proteins on IFN- α/β receptors have not been characterized as well as their IFN- γ receptor counterparts. Tyr 466 of IFN- α R1, along with surrounding residues, is needed for STAT2 binding to the subunit. In the case of IFN- α R2c, the constitutive STAT2 binding site has been mapped between amino acids 404 and 462. Further, multiple tyrosine residues throughout the intracellular domain of the IFN- α R2c are required for full signaling activation, but their precise role is still not fully known.

Effects of Signaling through the IFN- α/β Receptor

Type-I IFNs are considered to be antiviral interferons. They provide a vital signal for cells to mount a state of antiviral

defense. The antiviral state is achieved through the diverse actions of newly translated proteins made in response to the induction of hundreds of ISGs by IFN signaling. ISGs encode proteins that have effects ranging from cell-cycle arrest to the inhibition of translation and RNA degradation. Together, these effects serve to make the cell a very unfavorable environment for viral replication. Not surprisingly, cell lines and mice defective in type-I IFN receptors are much more susceptible to viral infection.

Intermediate Filament Linker Proteins: Plectin and BPAG1

P Fuchs and G Wiche, University of Vienna, Vienna, Austria

© 2013 Elsevier Inc. All rights reserved.

Glossary

Alternative splicing Mechanism to create different proteins (protein isoforms) from a common transcript by splice events using different exons or exon combinations.

Cytoskeleton Network of protein filaments in eukaryotic cells, which determines and influences cell shape and enables movement. Main components are actin filaments, MTs and IFs.

Knockout mouse Mutated mouse line harboring one or more defined mutations in a gene that lead to the inactivation of the gene product. Knockout mice are generated by embryonic stem (ES) cell and recombinant DNA technology.

Plakin protein family The plakin protein family, also referred to as the plakins, currently comprises plectin, BPAG1, MACF1, desmoplakin, envoplakin, periplakin, and

epiplakin. Plakins are structurally and functionally related proteins that, in most cases, can interact with more than one of the principal cytoskeletal filament systems. Common to all family members is the presence of at least one of two structurally highly conserved protein domains, the so-called plakin domain and the plakin repeat domain. The alternative designation suggested for plakins, cytolinkers (an abbreviation for cytoskeletal linker protein), is now being used to more broadly specify proteins with functions similar to those of plakins independently of sequence homology.

Protein isoforms Variant forms of a protein either generated by alternative splicing of a common transcript or as products of different members of a set of closely related homologous genes.

Plectin

The first identification of plectin as an interaction partner of intermediate filaments (IFs) was made three decades ago. The choice of its name (from *πλεκτή*, the ancient Greek word for net- or meshwork) was motivated by its microscopic visualization as part of a dense cytoplasmic network array in cultured cells.

Gene Locus and Isoform Diversity

In humans, the plectin gene is located on chromosome 8 and the murine ortholog on chromosome 15. The exon-intron organization of the plectin gene has been determined for man, mouse, and rat. Several plectin isoforms could be identified differing in their amino (N) termini. In the case of the mouse gene, alternative splicing of 11 different first exons into one common exon (exon 2) gives rise to a multiplicity of plectin variants (Figure 1). Additional alternative splicing of two small exons (2 α and 3 α) in the 5' area within the region coding for the actin-binding domain (ABD) increases the number of possible plectin isoforms. Furthermore, plectin transcript variants were identified that lack a single large exon encoding almost the entire α -helical coiled-coil rod domain of the molecule. Plectin isoforms are named after their alternative starting exons (e.g., plectin 1 and plectin 1a). However, the exact composition of the subsequent exons transcribed in each of the very large plectin messenger RNAs (mRNAs; ~11500–15500 nucleotides), especially in their very complex 5' part, has not yet been determined with absolute certainty.

Expression and Subcellular Localization

Plectin has been found to be expressed in virtually all mammalian tissues and cell types. It decorates different types of IFs, shows codistribution with their plasma membrane anchoring structures, and colocalizes with microfilaments (actin structures), primarily in peripheral areas of cells. It is associated with Z-lines of striated muscle, dense plaques of smooth muscle, intercalated discs of cardiac muscle, the basal cell-surface membrane (specifically hemidesmosomes) of keratinocytes, desmosomes of epithelial cells, and focal and fibrillary adhesions of various cultured cell types. Plectin has been identified also in cell layers separating tissues from fluid-filled cavities such as liver bile canaliculi, gut villi, kidney glomeruli, and endothelial cells of blood vessels. The expression patterns of plectin isoforms can vary considerably among different tissues and cell types, and certain isoforms are expressed in a tissue-specific or dominant manner, as revealed by quantitation of mRNAs isolated from different mouse organs. So, exon 1d-containing plectin transcripts were exclusively found in skeletal and heart muscle, whereas transcripts containing exon 1a are dominant in organs rich in epithelial cell types, such as lung, small intestine, and, in particular, skin. Intriguingly, the short alternative N-terminal sequences encoded by the different first exons were found to target isoforms to distinct subcellular locations. For instance, plectin 1a specifically associated with hemidesmosome-like structures, plectin 1b exclusively with mitochondria, and plectin 1f with vinculin-positive structures at actin stress fiber ends. Thus, it seems that a selection of plectin isoforms can be allocated to each cell type or tissue, providing a custom-made set of plectin-mediated functions to meet specific requirements of the particular cells. Consistent with such

Figure 1 Plectin and BPAG1 gene structures and alternative splicing of transcripts. Schematics shown represent mouse (plectin) and human (BPAG1) species. Alternative transcriptional start sites (arrows) and stop codons are indicated. Alternative start exons are shown as colored boxes, other exons as black boxes. Splicing is indicated by kinked lines for alternative exons or when exons are bypassed. Alternative single first exons and combinations of starting exons are designated with numbers and/or small letters, protein domains with capital letters. CH, calponin-homology domains forming the ABD; PD, plakin domain; RD, coiled-coil rod domain; PRDs, plakin repeat domains; MPR, modules of plectin repeats; SR, spectrin repeats; EF + GAR, EF-hand and GAR domain. Note that in the case of plectin isoform 1c, two transcriptional start sites at the beginning of noncoding exons are used with only one 1c-specific coding exon preceding exon 2 (common to all isoforms). Reproduced from Röper K, Gregory SL, and Brown NH (2002) The 'spectraplakins': Cytoskeletal giants with characteristics of both spectrin and plakin families. *Journal of Cell Science* 115: 4215–4225, with permission from The Company of Biologists.

a model, there is increasing evidence for individual isoforms carrying out distinct and specific functions.

Structural Properties

Considering just full-length versions of the protein, plectin has a molecular mass of 506–535 kDa depending on its first coding exon (Figure 2). The molecule has been visualized by electron microscopy as a dumbbell-shaped structure composed of a central rod domain flanked by two large globular domains. In these structures, two plectin polypeptide chains, most likely, are arranged in parallel, forming an α -helical coiled-coil central rod. Within the N-terminal part of each chain, plectin contains an ABD of the 'classical' CH1–CH2-type (i.e., containing two calponin-homology domains). The so-called plakin domain, which represents the defining feature of plakin protein family members, contains an SH3-like domain flanked by spectrin-type repeats. A rod-forming, ~1280-amino-acid-long, mostly α -helical segment precedes the C-terminal part of plectin, which comprises six tandemly arranged so-called plakin-repeat domains each containing a globular core structure, or module, and a surface-exposed linker domain. Plectin modules, similar to those of other plakins, consist of four complete and one incomplete tandem copies of a sequence motif, in databases referred to as plectin repeat. Forming a β -hairpin followed by two antiparallel α -helices, the plectin repeat structurally resembles a motif called ankyrin repeat that is found in a large number of proteins. It should be noted that plectin isoforms that are encoded by transcripts starting with noncoding first

exons, such as plectin 1h, 1i, and 1j, contain only truncated versions of plectin's ABD (Figure 2).

Molecular Interactions

Plectin binds to cytoplasmic IFs of different types via direct interaction with their subunit proteins, including vimentin, desmin, glial fibrillary acidic protein (GFAP), neurofilament proteins, and cytokeratins; binding has also been demonstrated to the nuclear IF protein lamin B. The major binding site for IF subunit proteins has been mapped to a short sequence in the linker segment between modules 5 and 6 in plectin's C-terminal domain. Plectin's highly conserved ABD close to its N terminus mediates binding not only to actin but also to the integrin subunit β 4, nesprin-3, dystrophin, utrophin, and vimentin. Additionally, the signaling molecule phosphatidylinositol-4,5-bisphosphate (PIP2) binds within the ABD, regulating plectin's interaction with actin. Actin (and integrin β 4) binding of plectin isoform 1a is also affected by calmodulin, which binds in a Ca^{2+} -dependent manner to the CH1 domain of its ABD. Additional integrin β 4- and β -dystroglycan-binding sites have been ascribed to plectin's plakin domain and to its C-terminal globular domain. The plakin domain of plectin also harbors a binding site for the hemidesmosomal protein BPAG2/BP180. Additionally, direct interactions of plectin with the membrane skeleton proteins fodrin and α -spectrin, the desmosomal protein desmoplakin, MT-associated proteins of the MAP2 and MAP1 subtypes, and BRCA2, a centrosome-associated tumor-suppressor protein have been reported. In line with the emerging

Figure 2 Schematic diagram of plectin and BPAG1 protein isoforms (mouse). Designation of isoforms (e.g., plectin 1a and BPAG1-e) and approximate molecular mass ranges are given (drawings are to scale). The blue diamond in front of full-length and rodless plectin stands for nine alternative N termini identified, the red diamond in front of BPAG1-n, -a, and -b for four alternative N termini identified. Note, that in case of BPAG1-n, one of the N-terminal variants symbolized by the red diamond is identical to BPAG1-e. For plectin three ABD variants exist, which are generated by alternative splicing of two additional exons (2 α and 3 α). In spite of the fact that only certain combinations of alternative first exons with exons 2 α and 3 α have been reported, it cannot be ruled out that all possible variants are existing. Note that in some isoforms of either one of the proteins, the ABD (typically consisting of two CH domains) can be truncated due to alternative splicing, resulting in a single CH domain. The plakin domains of plectin and BPAG1 are interaction domains consisting of ~10 spectrin repeats interrupted by an SH3-like domain. The plakin repeat domains each contain a globular module and a linker domain. Modules consist of four complete and one incomplete plectin repeats forming a complex globular domain. Linkers are considered as surface-exposed interaction domains, such as plectin's IF-binding site residing between plectin modules 5 and 6. Rod-like structures formed of spectrin repeats are present in BPAG1-a and -b. The GAS2-related (GAR) domain, named after the growth arrest specific protein 2, together with a glycine-serine-arginine (GSR)-rich domain (not indicated), has been suggested to mediate MT-binding.

concept that cytolinkers act as a platform for the assembly of complex protein machineries required for cytoskeletal rearrangements and intracellular signaling, plectin has been shown to be a target for a variety of serine/threonine kinases, including cell-cycle kinase Cdk1, and to interact with the receptor for activated C kinase 1 (RACK1), with the nonreceptor tyrosine kinase Fer, and energy homeostasis-controlling adenosine monophosphate-activated protein kinase. Whether the isoform-specific protein sequences located at the very N terminus of plectin variants can specifically select distinct binding partners or influence the affinities of other more distant modular-binding sites remains an open question.

Plectin Deficiency in Man and Mouse

In humans, mutations in the plectin gene lead to three forms of the disease epidermolysis bullosa simplex (EBS). Two of these, EBS with muscular dystrophy (EBS-MD) and EBS with pyloric atresia (EBS-PA) are autosomal recessive, one, EBS-Ogna, is dominant (Table 1). EBS-MD patients suffer from skin blistering and late-onset muscular dystrophy frequently leading to premature death in their third decade of life. In case of EBS-MD, only full-length plectin variants seem to be affected, whereas rodless variants are expressed at near-normal levels. In EBS-PA patients, where expression of all plectin isoforms is affected, the disease takes a more severe course. In this case, massive neonatal skin blistering and gastric abnormalities (pyloric or duodenal atresia) lead to early postnatal demise. EBS-Ogna was first described for a family from the Norwegian municipality of Ogna. It is caused by a site-specific mutation resulting in an exchange of a single amino acid residue (W to R) in plectin's ~1280-amino-acid-long rod domain. Patients suffering from this disease show skin fragility localized mainly to the limbs but no muscular symptoms.

Several mouse models have been generated to study the role of plectin *in vivo* and to provide animal models mimicking the clinical features of plectin-related EBS (Table 2). A first plectin-deficient mouse line, where all isoforms were inactivated in all cell types and tissues (plectin-null mouse), was followed by

several conditional knockout lines, in which the ablation of plectin was restricted to certain tissues and cell types, and by isoform-specific knockout lines. Homozygous plectin-null mice show a phenotype similar to EBS-MD, except that they die already 2–3 days after birth. In addition to severe skin blistering, compromised myofibril integrity in skeletal and heart muscle was detected already at this early stage.

In conditional knockout mice, where the ablation of plectin is restricted to keratin 5-expressing epithelia (K5-Cre cKO), skin blistering develops with a similar onset, body distribution, and severity as in plectin-null mice. Mice from both plectin knockout strains seem to die from malnutrition as a consequence of blistering of the oral epithelia, probably reducing the pups' desire for food due to pain, or obstruction of the oral cavity due to large blisters or cellular debris, or both. Mice with a conditional deletion of plectin in striated muscle (MCK-Cre cKO), develop progressive degenerative alterations in skeletal muscle, including aggregation and partial loss of desmin IF networks, detachment of the contractile apparatus from the sarcolemma, and decreased number and impaired function of mitochondria, thus, mimicking the late-onset muscular dystrophy typical of EBS-MD. Inactivation of plectin in nerve precursor cell-specific conditional knockout mice (nestin-Cre cKO) led to reduced motor nerve conduction velocity in sciatic nerve.

To reveal isoform-specific functions, a series of knockout mice was generated, each lacking just one of the isoforms, by deleting the corresponding N-terminal alternative isoform-specific sequences from the gene. All of these mouse lines turned out to be viable and fertile enabling comprehensive phenotyping. The absence of plectin isoform 1, an inner membrane-associated variant of plectin, led to alterations of the actin and IF cytoskeleton, impaired migration potential of fibroblasts and T cells, and reduced leukocyte infiltration during wound healing. Ablation of the outer mitochondrial membrane-associated plectin isoform 1b led to changes in the shape of the organelle probably by deregulation of the mitochondrial fusion–fission machinery. Inactivation of plectin 1c, the variant dominating in neural tissues, led to reduced motor

Table 1 Human disorders caused by plectin and BPAG1 mutations

<i>Genetic disease</i>	<i>Inheritance</i>	<i>Isoforms affected</i>	<i>Clinical signs</i>
<i>Plectin:</i>			
EBS-MD	Recessive	Full-length only ^a	Neonatal skin blistering and late onset, progressive muscular weakness
EBS-PA	Recessive	All ^a	Severe neonatal skin blistering and gastric abnormalities, early postnatal demise
EBS-Ogna	Dominant	Full-length only ^b	Localized skin fragility
<i>BPAG1:</i>			
Esophageal atresia and psychomotor retardation	Dominant, <i>de novo</i> reciprocal chromosomal translocation ^c	BPAG1-a, BPAG1-b	Encephalopathy, severe motor and mental retardation and delayed visual maturation
EBS	Recessive	BPAG1-e, BPAG1-n	Lifelong-generalized trauma-induced blisters and erosions. Neurological abnormalities? ^d

^aNot experimentally clarified for all mutations reported.

^bA heterozygote missense mutation in the rod-encoding exon 31 apparently derogates plectin functions in a dominant manner. Rodless variants should be unaffected.

^cSymptoms were first thought to be due to BPAG1-a and -b haploinsufficiency. As BPAG1 heterozygous mice show no symptoms it is more likely that dominant negative protein variants cause the symptoms observed.

^dWhether the observed neurological symptoms are a consequence of the reported BPAG1 mutation is uncertain.

Table 2 Mouse lines harboring plectin mutations

Designation of lines	Knockout type	Phenotypes (detected)
Plectin KO	Null ^a	Postnatal death at day 1–3, signs of starvation and growth retardation, internal and external skin blistering, skeletal muscle myopathy, and disintegration of intercalated disks in the heart
K5-Cre cKO, (<i>plec</i> ^{loxP/loxP} ; <i>Krt5-Cre</i>)	Conditional (stratified epithelia)	Postnatal death at day 1–3, signs of starvation and growth retardation, internal and external skin blistering
MCK-Cre cKO, (<i>plec</i> ^{loxP/loxP} ; <i>Ckm-Cre</i>)	Conditional (skeletal and heart muscle)	Progressive degeneration of skeletal muscle, aggregation of desmin IF networks, detachment of contractile apparatus from sarcolemma, decreased number and impaired function of mitochondria
Nestin-Cre cKO (<i>plec</i> ^{loxP/loxP} ; <i>Nes-Cre</i>)	Conditional (nerve precursor cells)	Reduced motor nerve conduction velocity in sciatic nerve
Plectin 1 KO	Isoform-specific ^b	Abnormalities of actin cytoskeleton and impaired migration of dermal fibroblasts, diminished chemotactic migration of T cells, reduced leukocyte infiltration during wound healing
Plectin 1b KO	Isoform-specific ^b	Shape changes of mitochondria in fibroblasts and myoblasts
Plectin 1c KO	Isoform-specific ^b	Reduced motor nerve conduction velocity in sciatic nerve, increased number of motor nerve fibers with small cross-sectional areas
Plectin 1d KO	Isoform-specific ^b	Necrotic, centrally nucleated, hypertrophic and atrophic skeletal muscle fibers; aggregation of desmin IFs and mitochondrial networks, compromised activities and lysis of mitochondria
Plectin 1d/desmin double KO	Double	Phenotypic characteristics similar to those of plectin 1d KO mice (partly more severe)

^aAll isoforms are inactivated in all cell types and tissues.

^bIsoform-specific KO mice lack only those transcript variants that start with a certain alternative first exon; expression of other isoforms is supposed to be unaffected.

nerve conduction velocity in sciatic nerve, reminiscent of the nestin-Cre cKO mice. Mice lacking plectin 1d, the Z-disk-associated isoform of plectin, showed all the characteristics of myofibrillar myopathies, including muscle fiber degeneration and aggregation of the desmin IF and mitochondrial networks, combined with compromised respiratory activity and lysis of mitochondria.

BPAG1

BPAG1 (alias BP230) and BPAG2 (alias BP180 or type XVII collagen) were originally identified in search of antigens with immunoreactivity to autoantibodies of patients suffering from bullous pemphigoid, an autoimmune subepidermal skin-blistering disease. Both proteins are components of hemidesmosomes but BPAG2, in contrast to BPAG1, harbors a collagenous extracellular domain and is not a member of the plakin protein family. The mouse ortholog of BPAG1 is also called dystonin in consideration of the fact that mutations in this gene cause sensory neuron degeneration in the mouse mutant *dystonia musculorum* (*dt*).

Gene Locus and Isoform Diversity

The BPAG1 gene in humans is localized on chromosome 6, and in mice, where it is referred to as dystonin, on chromosome 1. Similar to plectin, multiple exons in the BPAG1 gene are the basis of several protein isoforms generated by alternative splicing of transcripts (Figure 1). Four major variants (BPAG1-a, -b, -e, and -n) were specified showing clear differences in length and structure (Figure 2). In addition to this diversity, which is based on several combinations of structural domains, the variety of BPAG1 isoforms is further increased by

the existence of four alternative translation initiation sites for BPAG1-a, -b, and -n. Whether all variants of BPAG1, especially BPAG1-n, can be found in combination with all of these alternative N-terminal sequences is a matter of controversy. Moreover, like in the case of plectin, the exact composition of transcribed exons in BPAG1 mRNAs is often difficult to define due to the very large size of some of the transcripts.

Expression and Subcellular Localization

The epithelial isoform BPAG1-e is expressed primarily in basal epithelial cells where it colocalizes with hemidesmosomes. BPAG1-a is expressed at high levels in the nervous system, especially in dorsal root ganglia and spinal cord, while BPAG1-n, previously thought to be the dominant isoform in this tissue, seems to be minor compared to BPAG1-a. Isoform BPAG1-b is predominantly expressed in skeletal and cardiac muscle where it is found associated with Z-disks, and in developing mouse embryos it was also found in bone cartilage of the vertebrae. Of the four alternative N-terminal sequences so far identified, one is expressed only in epithelia whereas the expression profiles of the other three strongly varies in different tissues. There is some evidence that the very N-terminal alternative sequences of BPAG1 can determine the protein's localization within cells, similar to the case of plectin.

Structural Properties

The molecular masses estimated for BPAG1 isoforms vary from 302 kDa for BPAG1-e, 344 kDa for BPAG1-n, 615 kDa for BPAG1-a, to 824 kDa for BPAG1-b (Figure 2). Unlike plectin, all four isoforms of BPAG1 show considerable structural divergence. BPAG1-e contains an α -helical coiled-coil rod domain flanked by an N-terminal plakin domain and a C-terminal

region comprising two plakin-repeat domains. BPAG1-n overall is similar to BPAG1-e, except for containing an additional N-terminal ABD of the CH1-CH2-type, which in one variant is truncated, comprising only the CH2 domain. BPAG1-a, starting with an ABD followed by a plakin domain, resembles BPAG1-n at its N terminus, but differs regarding the rest of the molecule. Its rod domain consists of up to 28 spectrin repeats and its C-terminal domain contains EF-hand Ca^{2+} -binding motifs followed by a region including a GAS2-related (GAR) protein domain. BPAG1-b exhibits structural features similar to BPAG1-a, except for an additional pair of closely adjoined plectin repeat modules of unknown function located between the plakin domain and the spectrin repeats.

Molecular Interactions

Because of its large size and structural diversity, BPAG1 can be expected, like plectin, to have not only a variety of interaction partners but also different sets of binding partners for each isoform. Via their N-terminal CH1-CH2-type ABD, BPAG1 isoforms can associate with filamentous actin. However, some of its isoforms, which due to alternative splicing within the ABD, express only one of the two CH domains (Figure 2), lack this ability. This truncation has been suggested to activate a MT-binding site located within the plakin domain of BPAG1 that otherwise remains cryptic. In addition, the C-terminal GAR and the GSR-containing domains have been suggested to mediate interactions with microtubules. The location of IF-binding sites within the C-terminal plakin-repeat domains of BPAG1-e and -n has been confirmed for keratin and neurofilaments, and BPAG2 and ERBIN, a specific Erb-B2 tyrosine kinase receptor-binding protein, have been shown to interact with BPAG1's plakin domain. Furthermore, BPAG1-a was found to directly interact with dynactin p150^{Glued} and the endosomal vesicle protein retrolinkin, while BPAG1-b was reported to interact via its N terminus with plectin and α -actinin.

BPAG1 Deficiency in Man and Mouse

In humans, so far only a couple of mutations have been identified in the BPAG1 gene (Table 1). In one reported case, a 4-year old, suffering from a defect in the BPAG1 gene caused by a *de novo* reciprocal translocation, showed signs of nonprogressive encephalopathy, severe motor and mental retardation, and delayed visual maturation. The BPAG1 isoforms affected in this case probably were BPAG1-a and -b, but as the chromosomal alteration was restricted to only one allele, it is not clear whether the symptoms observed were due to a gain or loss of function. In a second case reported, a 38-year-old patient with a homozygous nonsense mutation within the exon encoding the coiled-coil rod domain of isoforms BPAG-e and -n suffers from lifelong-generalized trauma-induced blisters and erosions, a condition which is now classified as a new form of autosomal recessive EBS. Whether the additional neurological abnormalities of these patients are caused by the BPAG1 mutation remains unclear. The role of autoantibodies to BPAG1 found in patients suffering from bullous pemphigoid could be further elucidated by showing that BPAG2, not BPAG1, is the primary autoantigen critical for disease development.

Table 3 Mouse lines harboring BPAG1 mutations

Designation of lines	Knockout type	Phenotypes detected
<i>Dystonia musculorum</i> (<i>dt</i>) ^a	Natural and spontaneous mutants ^b	Sensory neuron degeneration culminating in death 3–5 weeks after birth, defects in muscle and neuron cytoarchitecture and in skin integrity, accumulation of organelles in focal axonal swellings ^c
BPAG1 KO	Null ^d	Deterioration in motor function, sensory neuron degeneration, skin blistering upon mechanical trauma; life expectancy similar to that of <i>dt</i> mice

^aSeveral allelic variants.

^bMutations in the different *dt* mouse lines most likely affect different BPAG1 isoforms.

^cDifferent *dt* lines show similar, but not identical phenotypes.

^dIn the BPAG1-null line, all major isoforms of BPAG1 are affected.

In mice, deletions in the BPAG1 gene cause the disorder *dt*, an autosomal recessive neuropathy (Table 3). At the age of 1–2 weeks, homozygous *dt* mice display progressive loss of limb coordination caused by degeneration of sensory neurons. Dorsal root ganglia axons exhibit disorganization of neuronal IFs and MT networks accompanied by abnormal axonal myelination and axonal swellings. It has been suggested that swellings result from defective axonal transport caused by MT disorganization. Additional defects in Schwann cell and myocyte functions have been reported for these mice. Not all *dt* mouse strains, however, lack the BPAG1-e isoform. Independent of the *dt* mice, most of which carry spontaneously arisen BPAG1 mutations, a BPAG1-defective mouse strain was generated using gene-targeting techniques. This mutation eliminates the exons encoding the plakin domain of BPAG1 (common to all isoforms) and, therefore, is considered as null allele. In addition to the phenotypic characteristics of some *dt* mouse strains, BPAG1-null mice show fragility of skin upon mechanical stress. Based on these findings it is assumed that the absence of BPAG1-e is responsible for the observed skin abnormalities, deficiency in BPAG1-a accounts for the neuronal deficits, and lack of BPAG1-b could be the reason for muscle defects.

Intermediate Filaments

K M Bernot and P A Coulombe, Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD, USA

Glossary

Intermediate filament (IF) Filaments of 10–12 nm width and several microns in length found in the nucleus and the cytoplasm, where they form the cytoskeleton along with actin microfilaments and microtubules.

Nuclear lamina A scaffold-like network of lamin intermediate filaments apposed against the inner membrane of the nuclear envelope.

Trigger motif Small group of amino acids required for stabilization of an alpha helix and nucleation of dimer formation through coiled-coil interactions.

Unit length filament (ULF) Late-stage intermediate during the assembly of cytoplasmic IFs, which is ~60 nm in length and consists of eight tetramers (32 monomers) annealed laterally.

Intermediate filaments (IFs) are intracellular fibrous polymers that became a prominent constituent of the cytoskeleton coinciding with the appearance of multicellular life. They are readily distinguishable from actin microfilaments (6–8 nm) and microtubules (25 nm) by virtue of their diameter (10–12 nm). In mammals, >70 genes encode proteins able to self-assemble into IFs. A small subset of these genes encodes lamins, the building blocks of the nuclear lamina, whereas all others encode cytoplasmic proteins. A major function shared by all IFs is to endow cells and tissues with a unique ability to resist trauma – this contribution is important in structures (e.g., axons and nuclei), cells, and tissues exposed to significant stress. Additional important roles in regulating cell growth and proliferation, cell death, cell migration, and response to stresses are manifested in a IF protein- and context-specific manner.

Features of IF Proteins

As a group, IF proteins are very heterogeneous in size (40–240 kDa), charge, and various other properties (Table 1). The property of self-assembly is hard-wired into the characteristic tripartite domain structure shared by all IF proteins (Figures 1(a) and 1(b)). The central domain, an extended α -helix featuring long-range heptad repeats interrupted at three conserved locations, is the main determinant of self-assembly. This rod domain comprises 310 and 352 amino acids in cytoplasmic and nuclear IF proteins, respectively, and is bordered by invariant, signature ~15-mer sequences. Flanking sequences at the N- and C-termini of the central rod domain are key in conferring each IF protein its individuality. Most IFs are heteropolymeric *in vivo*, although several IF proteins can *de facto* self-assemble into filaments as homopolymers *in vitro*.

Almost all metazoans (animals) contain both nuclear and cytoplasmic IFs, with the notable exception of arthropods, which contain only lamins. The presence of an exoskeleton, along with an increased density of microtubules in cells subjected to stress, may account for the absence of cytoplasmic IFs in arthropods. Phylogenetic analyses suggest that IFs initially appeared in the nucleus and later moved to the cytoplasm during evolution.

IFs have not been found in plants, fungi, or protists, with one exception: there is evidence for an IF-like system in *Caulobacter crescenti*. Most IFs are intracellular proteins; rare exceptions include the hagfish IFs, which are secreted polymers.

Assembly, Structure, and Regulation of IFs

Assembly and Structure

Owing to the long-range heptad repeats present within their central α -helical domain, IF proteins readily dimerize through coiled-coil interactions. In the dimer, individual rod domains are aligned in parallel and in register (owing to controlled nucleation by a trigger motif) (Figure 1(b)). Nuclear and cytoplasmic IFs differ in the formation of tetramers. Lamin dimers associate in a head-to-tail fashion to form thin longitudinal strands, several of which laterally associate with an antiparallel orientation to form mature filaments. Dimers of cytoplasmic IFs, on the other hand, interact along their lateral surfaces with an antiparallel orientation to form compact tetramers. These tetramers continue to favor lateral interactions as they further polymerize to form an ~60-nm long unit-length filament (ULF). Annealing of ULFs produces mature 10–12 nm filaments whose length can reach >10 μ m. Mature IFs lack an obvious structural polarity (see Figure 1(c)), reflecting the antiparallel orientation of dimers within them. While models for idealized IFs usually include 32 monomers per filament cross-section, mass per-unit length determinations revealed that in actuality, this number varies a fair amount depending on the source and type of IFs. This heterogeneity is still unexplained. There is as yet no satisfactory model for the high-resolution structure of IFs.

Unlike actins and tubulins, IF proteins do not bind or metabolize nucleotides. They do not require an external input of energy or cofactor for assembly *in vitro*. They readily assemble into filaments when ectopically expressed in a virtually any cell type in culture, suggesting that the process does not require specialized factors *in vivo*. Cytoplasmic IF networks often extend from the perinuclear area to the cell periphery (Figure 1(d)), although there are many instances in which IFs are concentrated in specialized regions of the cell. Such is the case for keratins in

Table 1 The intermediate filament family

IF type	Protein name	No. genes	Protein MW	Assembly group ^a	Tissue distribution	Association with human disease ^b
I	Keratins (acidic)	28	40–64	A	Epithelia	Multiple skin fragility diseases Oral and cornea fragility diseases Hair disorders Inflammatory bowel disease ^c Cryptogenic cirrhosis ^c Nearly identical to type I keratins
II	Keratins (basic)	26	52–68	A	Epithelia	
III	Vimentin	1	55	B	Mesenchyme (esp. early develop.)	None known
	Desmin	1	53	B	Muscle	Distal myopathy; cardioskelet. Myop.

^aWithin each group, proteins heteropolymerize in either an obligatory or facultative fashion to form filaments.

^bMutations affecting IF-coding sequences are causative in the diseases listed unless indicated otherwise.

^cMutations in either K8 or K18 have been identified as risk factors for these conditions.

^dAssociation needs to be confirmed in additional patients.

polarized epithelial sheets, desmin in myocytes, and neurofilaments in axons. In the cytoplasm, IFs can interact with F-actin, microtubules, and specific adhesion-mediating complexes. While the relative importance of these interactions varies between IF proteins and cell types, their dominant influence on IF organization has been established through experiments in which these elements were disrupted.

Regulation

Both nuclear and cytoplasmic IFs are disassembled and/or profoundly reorganized during mitosis. Both of them can also be dynamically remodeled under steady-state conditions in noncycling cells. *In vivo* experiments utilizing green fluorescent protein (GFP)-tagged vimentin or keratin suggest that filament formation is initiated at the cell periphery whereas the subunit exchange fueling steady-state dynamics possibly occurs along the filament wall. More information about these crucial aspects of IF biology is needed. Posttranslational modifications play a key role toward the regulation of the assembly and disassembly of IFs *in vivo*, and of their interaction with

associated proteins. Thus, all IF proteins are subject to phosphorylation at multiple sites, and the kinase, target site(s), and significance have been deciphered in many instances. The molecular basis of steady-state polymer dynamics, which have been tied to nucleotide metabolism for F-actin and microtubules, remain unresolved for IFs. Possibly, rapid cycles of IF protein phosphorylation–dephosphorylation could enact the reversible conformational change needed. In addition, specific IF proteins have been shown to be O-glycosylated, ubiquitinated, and/or sumoylated, or modified in other ways, though the underlying significance remains unclear in many cases. Lamins undergo lipid modification and enzymatic processing of their C-terminus, reflecting their association with the inner nuclear membrane.

Dissecting the IF Superfamily

Most of the >70 genes forming the IF superfamily can be easily classified into one of five sequence types based on gene

Figure 1 (a) Diagram illustrating the domain substructure of IF proteins. Rectangles depict central α -helical rod domain (1A, 1B, 2A, and 2B) separated by short, nonhelical linkers (L1, L12, and L2). The rod domain is flanked by nonhelical head and tail domains. Two highly conserved regions critical for the nucleation of coiled-coil dimer formation (trigger motifs) are darkly shadowed. The numbers represent amino acid residues in human vimentin (Strelkov et al. 2003 *Bioessays* 25: 243–251.) (b) Diagram illustrating the architecture of the human vimentin dimer, as determined by X-ray crystallography (1A and 2B subdomains, dark gray) or modeling (light gray) (Strelkov et al. 2003 *Bioessays* 25: 243–251.) (c) Keratin IFs reconstituted *in vitro* from purified proteins and visualized by negative staining and electron microscopy. These filaments appear as smooth-surfaced, apolar, flexible polymers of ~ 11 nm in width and several microns in length. Scale = 250 nm. (d) Visualization of keratin IFs by indirect immunofluorescence in primary cultures of mouse skin keratinocytes. The filaments form a network extending from the surface of the nucleus (N) to the cytoplasmic periphery in these two cells. Scale = 30 μ m. (e and f) Visualization of neurofilaments in axon processes. (e) Thin-section transmission electron microscopy, showing neurofilaments viewed in cross-section. Neurofilaments (arrows), microtubules (arrowheads), and mitochondria (M) can be distinguished. Scale = ~ 250 nm. (Garcia et al. 2003 *Journal of Cell Biology* 163: 1011–1020.) (f) Quick-freeze deep-etch electron microscopy of axoplasm along its main axis. Neurofilaments (arrows) fill the axoplasm, and numerous cross-bridges (arrowheads) between the filaments can be seen. Scale = 100 nm. (Hirokawa et al. 1984 *Journal of Cell Biology* 98: 1523–1536.) (g–i) Visualization of lamins in the nucleus. (g) Native nuclear lamina of *Xenopus* oocytes. Preparation of Triton X-100-extracted nuclear envelope by freeze-dried/metal-shadowing reveals the meshwork basket weave of the nuclear lamina and the array of nuclear pore complexes (arrowheads). Scale = 1 μ m. (Aebi et al. 1986 *Nature* 323: 560–564.) (h and i) GFP-tagged Lamin B (h) or A (i) was introduced into mouse embryonic fibroblasts. Live cells in interphase show bright fluorescence around the nuclear rim while a fainter veil of fluorescence is visible in the nucleoplasm. Scale = 10 μ m. (Moir et al. 2000 *Journal of Cell Biology* 151: 1155–1168.)

structure and nucleotide homology over the central alpha-helical domain. Individual members within each sequence type are often related in their tissue distribution. The remaining sequences defy classification and have been assigned to a sixth, orphan group of sequences (see below).

Type I and Type II Keratins

Type I and type II IFs are part of the keratin (or cytokeratin) family of proteins found in all epithelia. The human genome features 54 functional keratin genes, with 28 type I and 26 type II keratin genes (see [Table 1](#)). Type I keratins tend to be smaller and acidic compared to the larger, neutral–basic type II keratins. Keratin assembly proceeds strictly from type I to type II heterodimers, accounting for the duality of sequences as well as their pairwise regulation *in vivo*. While any combination of purified type I and type II keratin proteins yields a fibrous polymer *in vitro*, specific pairs are coregulated in a fashion directly related to epithelial tissue type and/or differentiation state *in vivo*. In mammals, specific type I–type II gene pairings occur in simple (e.g., liver and GI tract), complex (e.g., skin and oral mucosa), and hard epithelia (e.g., hair and nail), with little overlap. Quite remarkably, moreover, specific type I–type II gene pairs are differentially and sequentially expressed in progenitor (mitotically active), early, and late differentiation stages in a host of epithelia. The conservation of keratins in terms of primary structure and distribution suggests an important role in epithelial diversity – this role as determinant of tissue specificity is emerging from detailed studies of transgenic models in which select IF genes are manipulated.

Type III IFs

The type III group consists of vimentin, desmin, glial fibrillary acidic protein (GFAP), peripherin, and syncoilin ([Table 1](#)). Vimentin is widely expressed during development, but typically gives way to other IF proteins during differentiation. Accordingly, vimentin, which is an assembly competent on its own, is usually found in co-polymers with other type III, type IV, or orphan sequences in mature cell types. Vimentin persists as the dominant cytoplasmic IF protein in fibroblasts, endothelial cells, adipocytes, macrophages, lymphocytes, and neutrophils. Desmin is found in the cytoplasm of smooth muscle and is concentrated at the Z lines of skeletal and cardiac muscle. Several variants of GFAP arise from a single precursor messenger RNA (mRNA), and occur in the astrocytes of the central nervous system and in Schwann cells of the peripheral nervous system (PNS). Peripherin occurs in the post-mitotic neurons of the PNS, whereas syncoilin is an intrinsic component of the dystrophin-associated protein complex in skeletal and cardiac muscle.

Type IV Neurofilaments

This group occurs specifically in neurons and consists of the neurofilament triplet proteins NF-L, -M, and -H, and α -internexin. NF-L (light), NF-M (medium), and NF-H (heavy) co-polymerize obligatorily in a 5:3:1 ratio to form filaments with a core diameter of 10–12 nm and unusual side arms projecting >20 nm away ([Figure 1\(f\)](#)). These side arms

represent the extended C-terminal tails of NF-M and NF-H, which feature a large number of Lys–Ser–Pro repeats that adopt an elongated shape when stoichiometrically phosphorylated. Neurofilament proteins are synthesized in the cell body of neurons and transported to the axon, where they contribute to the determination of axon caliber owing to their side arm projections ([Figure 1\(f\)](#)). α -Internexin, on the other hand, is expressed at an earlier stage of neuronal differentiation and homopolymerizes into IFs that may thereafter scaffold the assembly of NF-L, M, and H, synthesized late during differentiation.

Type V Lamins

Nuclear lamins constitute the type V IFs. Consistent with their unique distribution within the cell, lamin proteins contain a canonical nuclear localization signal within their C-terminal tail and a CAAX-box at their C-terminus which, after farnesylation and carboxyl-methylation, mediates membrane anchorage. The C-terminus of lamin A is a novel β immunoglobulin-like fold that acts as a docking site for several lamin-associated proteins, and its alteration causes disease ([Table 1](#)). In addition, lamins feature six extra heptad repeats within the α -helical subdomain 1B of the rod, the significance of which is unclear. The presence of these six extra heptads in the cytoplasmic IF proteins of invertebrates has lent strong support to a proposal that the ancestral IF gene was lamin-like in character.

There are two major types of lamins, designated A and B. B-type lamins, which are essential in all species tested to date, are found in all somatic and germ cells. The mammalian *Lmna* locus yields four distinct proteins; the two major ones, A (664 a.a.) and C (573 a.a.), are identical over residues 1–566 and differ at their C-termini owing to alternative splicing of a common precursor mRNA. The *Lmna* products occur preferentially in differentiated cells. Lamins form a meshwork structure called the ‘nuclear lamina’ just beneath the inner nuclear membrane ([Figure 1\(g\)](#)), where they interact with several key constituents of that membrane. In addition, lamins also occur in the nucleoplasm, with a mixed organization as a diffuse network and in focal clusters ([Figures 1\(h\)](#) and [1\(i\)](#)).

Orphan IFs

Several orphan IFs exist that do not easily fit into any other group ([Table 1](#)). These tend to show a very restricted tissue distribution. Exclusive to differentiated lens fiber cells, phakinin (also called CP115) and filensin (also called CP49) coassemble in a 3:1 molar ratio to produce a unique structure called ‘beaded filaments’, where 20-nm-wide beads decorate the otherwise 8-nm-wide filament in a regularly spaced pattern. Nestin was originally discovered as a marker of neuroepithelial stem cells, but is now known to exhibit a broader distribution including various multipotent progenitor cells. It is incorporated into filaments at very low stoichiometry compared to others IF proteins. Synemin, desmuslin, and paranemin coassemble with type III IFs (notably desmin) in muscle, with varying stoichiometry. Just like NF-M and NF-H, nestin, synemin, and paranemin have unusually long C-terminal tail domains that influence interaction between IFs and with other elements of the cytoskeleton.

Functions of IFs and Their Involvement in Disease

Resistance to Stress

A major, family-wide function of IFs is to endow cells and tissues with a resilient and yet flexible scaffold needed to withstand mechanical, and in some cases nonmechanical, stresses. This concept first came to light from studies in which transgenic mice expressing a mutant epidermal keratin developed severe epidermal blisters. Subsequent analysis of DNA from patients with epidermolysis bullosa simplex, an epidermal blistering disease, revealed mutations in epidermal keratins, confirming the link between mutant IF proteins and inability of cells to withstand mechanical stress. Since then, the importance of IFs and resistance to various trauma has been extended to a variety of cell types including myocytes, fibroblasts, astrocytes, and trophoblasts. In the absence of stress, these cells usually tolerate the expression of a mutated, defective IF protein even though it may lead to disorganization of their IF network. In the event of shear stress, however, the intracellular rupture of such mutant-expressing cells reveals their unusual fragility. These features can also be observed in the absence of one or more keratins, as is evidenced by the fragility of the oral mucosa in *Krt6 α / β* null mice (Figures 2(a) and 2(b)) and disruption of the keratin IF network in cultured primary keratinocytes from these mice (Figures 2(c) and 2(d)). Studies of the micromechanical properties of IF assemblies *in vitro* and in live cells in culture showed that they exhibit properties that are uniquely suited to fulfill this crucial role, and

that inherited mutations compromise these properties. The diversity of IF sequences and their differential expression may serve, at least in part, the purpose of achieving the right compromise between properties of pliability and resilience given the context-specific demands placed upon a cell or its constituents.

Insight from Laminopathies

Nuclear lamins offer tantalizing clues for additional functions. Multiple lines of evidence, adeptly reviewed in recent texts, show that the nuclear lamina participates in determining the shape, size, and integrity of the nucleus, along with the number and positioning of nuclear pores. For example, *Lmna* null mice exhibit severe growth retardation and features of muscular dystrophy (Figures 2(e)–2(h)). Inherited mutations in the *Lmna* gene are now known to give rise to a variety of clinical disorders (Table 1), which from a bird's eye view seem very distinct from one another. Premature aging conditions such as Hutchinson–Gilford progeria syndrome and atypical Werner syndrome are examples of relatively recent, and unanticipated, entries in the realm of laminopathies. While fragility of the nuclear envelope could possibly account, at least in part, for the pathogenesis of the muscle-based laminopathies, other mechanisms must be invoked for the premature aging conditions and related disorders. Among the likely possibilities are alterations in the control of gene expression and perturbations in the composition and function of the endoplasmic

Figure 2 (a and b) Hematoxylin-eosin stained, paraffin-embedded section of wild-type (a) and *K6 α /K6 β* double null (b) mouse tongues. Tissue is oriented along its anterior-posterior axis. In the absence of the K6 proteins α and β , the posterior region of the tongue epithelium develops severe blistering owing to the fragility of filiform papillae (FP). Scale = 200 μ m. Several null cells (–/–) feature disrupted keratin IF networks (see arrowheads). Scale = 50 μ m. (Wong and Coulombe 2003 *Journal of Cell Biology* 163: 327–37.) (e and f) Aberrant localization of nuclei in muscle from *Lmna* null mice. (e) Hematoxylin-eosin stained, paraffin-embedded sections through wild-type perivertebral muscle show the peripheral localization of the nuclei in the muscle fibers. (f) In *Lmna* null muscle, myofibrils (Mf) are irregularly sized, and there is an increase in the number of nuclei, many of which are centrally located within the muscle fibers (arrows). Scale = ~15 μ m. (Sullivan et al. 1999 *Journal of Cell Biology* 147: 913–920.) (g and h) Immunohistochemical analysis of wild type and *Lmna* null mouse embryonic fibroblasts in culture. After fixation with 3% paraformaldehyde, the nuclei were labeled with DAPI (blue) and indirect immunofluorescence of Lamin B (red). Note the uniform distribution of this protein in wild-type nuclear envelopes (g), but its loss from one pole of the irregularly shaped nuclei in the *Lmna* null cells (h). Dashed line indicates boundary of nucleus. Scale = ~10 μ m. (Sullivan et al. 1999 *Journal of Cell Biology* 147: 913–920.)

reticulum, which extends into and communicates with the nuclear envelope. An impact on gene expression could result from lamins' potential involvement in basic nuclear processes such as chromatin organization, DNA replication, RNA processing, and nucleocytoplasmic exchange.

Apoptosis

Just like their nuclear counterpart, cytoplasmic IFs have evolved the ability to organize, through scaffolding, proteins and factors involved in signaling and other metabolic processes. Such interactions, for instance, clearly modulate the response of various types of cells to pro-apoptotic signals. Absence or disruption of one or more IFs in several cell types (simple epithelial cells lacking K8, keratinocytes lacking K17, and neurons containing peripherin aggregates) render cells significantly more likely to undergo apoptosis in response to tumor necrosis factor- α (TNF α) or Fas. In simple epithelial cells lacking K8, this occurs in part because K8/18 IFs contribute to the targeting of Fas receptors to the cell surface, and bind to the cytoplasmic tail domain of TNFR2, and to death domain-containing proteins such as TRADD and DEDD. In addition to influencing the decision to undergo apoptosis, IF proteins are also key in its proper execution through their caspase-mediated degradation.

Spatial Organization

Recent evidence points to a role for IFs toward spatial organization within the cell. Keratin IFs can influence the sorting events leading to the organization of the apical pole in polarized epithelial cells, and vimentin IFs promote the association of the sodium–glucose cotransporter SGLT1 with lipid rafts, and its activity, in renal tubular cells. The contribution of neurofilaments toward the radial growth of neurons, itself a crucial determinant of conduction velocity, represents another example of how IFs can promote an asymmetric cytoarchitecture. The notion that cytoplasmic IFs promote some form of spatial organization is quite surprising given their nonpolar character – the spatial code required might be provided by site-specific, dynamic phosphorylation events, and regulated interactions with associated proteins. Future efforts should lead to a broader appreciation of the many metabolic processes influenced by IFs and underlying mechanisms of how inherited IF mutations cause disease.

Cell Proliferation, Growth, and Migration, and Tissue Inflammation

The ability of several IF proteins to interact with various classes of cellular proteins (e.g., 14-3-3 adaptor proteins) accounts for their impact, again in a sequence-dependent and

context-specific fashion, toward the regulation of cell-cycle progression as well as protein synthesis, which represent key determinants of tissue growth. Yet another way in which IF proteins, and keratin in particular, can impact cell and tissue growth is via their ability to modulate, in a cell-autonomous fashion, the expression of select pro-inflammatory cytokines and chemokines. Finally, several IF proteins including vimentin, nestin, and various keratins, have been shown to impact cell migration in the physiological settings of tissue repair and/or inflammation, and in diseases such as cancer.

Glossary

cADPR An intracellular messenger derived from NAD⁺ acting on the ryanodine receptor as an agonist or a modulator.

IP₃ A second messenger derived from the cleavage of PIP₂ (phosphatidylinositol 4,5-bisphosphate) by phospholipase C which interacts with IP₃-sensitive Ca²⁺ channels causing calcium release.

NAADP An intracellular messenger derived from NADP⁺ acting on a yet unknown intracellular Ca²⁺-release channel.

Second messenger An intracellular molecule whose concentration is regulated in response to binding of a specific ligand to an extracellular receptor to transduce information.

Structure of NAADP

Nicotinic acid adenine dinucleotide phosphate (NAADP) is a pyridine nucleotide similar to nicotinamide adenine dinucleotide phosphate (NADP), except for the amide group of the nicotinamide ring, which in the NAADP molecule is replaced by a carboxyl group (Figure 1). Despite this small difference, in sea urchin eggs (the model system used to characterize this molecule), NADP is devoid of any Ca²⁺-release efficacy, suggesting that the binding site specifically recognizes this region of the molecule as a discriminator and that NAADP is not just a cellular surrogate for NADP.

NAADP-Induced Ca²⁺-Release in Invertebrates and Plants

Although the chemical existence of NAADP was reported by Bernofsky in 1980, the possibility that NAADP could be a putative intracellular messenger was hypothesized by Lee and co-workers. In 1987, they described the presence of a contaminant in commercially available NADP that could release Ca²⁺ in sea urchin eggs. Only in 1995, this contaminant was shown to be NAADP. NAADP has now been found to be a potent Ca²⁺-releasing agent in various invertebrate systems including starfish, sea snails, and sea squirts (see Table 1). Furthermore, NAADP has also been shown to release Ca²⁺ from microsomes prepared from plant preparations. Although the NAADP receptor has not yet been cloned, it presumably is a Ca²⁺ channel distinct from those described to date, as indicated by numerous biochemical evidences. Nonetheless, in a few systems, such as the skeletal muscle, NAADP might also use the ryanodine receptor as a mediator of its effect. In sea urchin eggs, the best characterized model to date, NAADP releases Ca²⁺ via an intracellular channel that is distinct from those that are responsive to inositol 1,4,5-triphosphate (IP₃) and cyclic ADP ribose (cADPR). NAADP-induced Ca²⁺ release does not exhibit any cross-desensitization with the other two mechanisms. Furthermore, it is not sensitive to heparin, ruthenium red or high concentrations of ryanodine, antagonists of the IP₃, and ryanodine channels. According to the concentrations, Ca²⁺ can both

activate and inhibit IP₃ and ryanodine receptors, providing a means of modulation of the channel independent of ligands. A major difference between the NAADP mechanism and the other two is the insensitivity of the NAADP-induced Ca²⁺ release to both cytosolic and vesicular Ca²⁺ concentrations. Furthermore, other differences exist in the channels in regard to the pH sensitivity, ion dependency, endogenous modulators, and kinetic features. Finally, specific NAADP-binding sites, insensitive to IP₃ and cADPR, have been shown in sea urchin egg microsomes.

All the efforts done to characterize the pharmacology have failed so far to produce a valid antagonist of the NAADP-sensitive mechanism. In echinoderms, it has been shown that L-type Ca²⁺-channel antagonists (and BayK8644, an agonist) are able to inhibit NAADP-induced Ca²⁺ release, but this occurs just at concentrations, which are approximately 100-fold higher than those able to inhibit voltage-operated Ca²⁺ channels. Nonetheless, it has been found that NAADP itself can be used as an antagonist since in sea urchin eggs subthreshold concentrations of this nucleotide are able to completely abrogate the calcium release caused by further NAADP elevations. Neither IP₃ nor cADPR are regulated by this mechanism and so far the significance of this process is unknown.

In sea urchin eggs, the NAADP-sensitive channel does not appear to reside on the same intracellular organelles compared to IP₃ and ryanodine receptors, as shown by membrane separation experiments. To support this, while IP₃- and cADPR-induced Ca²⁺ release are completely abolished by pretreatment of homogenates with thapsigargin, a poison of the Ca²⁺ pump that is responsible for the accumulation of Ca²⁺ in the endo(sarco)plasmic reticulum, NAADP-induced Ca²⁺-release appears to be unaffected. Recently, it has been shown that, at least in this system, the organelle on which the mechanism might reside is the reserve granule, the egg equivalent to lysosomes. Whether this will be a general feature of this mechanism across species remains to be established.

In sea urchins, starfish, and sea squirts (invertebrate systems) where the properties of NAADP on Ca²⁺ release have been investigated in intact cells, it has been shown that this Ca²⁺-release mechanism does not act in isolation from the others, but instead appears to work in concert to elicit specific responses. For example, in starfish NAADP-induced Ca²⁺ release

Figure 1 Structure of nicotinic acid adenine dinucleotide phosphate.

Table 1 Models described to be responsive to NAADP between 1995 and 2002

Species	Model	NAADP effect
Sea urchin	Intact egg, microsomes	Inactivation (<1 nM, IC ₅₀ 200 pM), agonist (>3 nM, EC ₅₀ 25 nM), inactivation (<1 nM, IC ₅₀ 200 pM), agonist (>3 nM, EC ₅₀ 25 nM)
Starfish	Intact egg	Agonist (1–2 μM)
Sea squirt	Intact oocyte	Agonist (EC ₅₀ 30 nM)
Sea snail ganglia	Presynaptic neuron	Agonist (10–50 μM)
Red beet	Microsomes	Agonist (96 nM)
Cauliflower	Microsomes	Agonist (1 μM), inactivation (3 nM)
Frog neuromuscular junction	Nerve terminal	Agonist (10 μM to 1 nM; liposomal delivery)
Human β pancreatic cells	Intact cells	Agonist (100 nM), inactivation (10 μM)
Human T-lymphocytes	Intact cells	Agonist (max 100 nM), inactivation (10 μM)
Mouse pancreatic acinar cells	Intact cells	Agonist (50 nM), inactivation (1–100 μM)
Rat pulmonary smooth muscle cells	Intact cells	Agonist (10 nM), inactivation (100 μM)
Rat fibroblast cells	Microsomes	Agonist (10 μM)
Rat brain	Microsomes	Agonist (EC ₅₀ 1 μM)
Rabbit heart	Microsomes	Agonist (EC ₅₀ 320 nM)
Rat mesangial kidney cells	Microsomes	Agonist (EC ₅₀ 4 μM)
A7r5, HL-60, H9c2 cell lines	Microsomes	Agonist (10 μM)

appears to be partially inhibited by the co-injection of IP₃ and ryanodine receptor antagonists, suggesting that the NAADP-induced cytosolic calcium elevations are due to both release from the NAADP channel and to amplification through IP₃ and ryanodine receptors. The extent and the manner of the cross-talk appears to be different from one system to another, but it is one of the conserved features of NAADP signaling through evolution, since it has been observed also in vertebrate systems.

NAADP-Induced Ca²⁺-Release in Vertebrates

Both microsomal and intact systems from vertebrate models have been shown to respond to NAADP (Table 1).

Furthermore, binding sites with nanomolar affinity for NAADP have been described in brain and cardiac tissues. In similar fashion to what is observed in invertebrate systems, NAADP-induced Ca²⁺ release is distinct from the IP₃ and ryanodine-mediated mechanisms when it is investigated in microsomal preparations, while in intact systems there appears to be a high degree of overlap. One of the differences observed between vertebrates and invertebrates is that the unusual desensitization property observed in sea urchin eggs does not seem to have been conserved in vertebrates. Instead, in many of the systems described (e.g., pancreatic acinar and β-cells, T-lymphocytes), NAADP appears to release Ca²⁺ in an inverted bell-shaped curve, with high concentrations unable to have any effect. Observations of cross-talk between NAADP-induced Ca²⁺ release and IP₃ and ryanodine receptors in pancreatic acinar cells and T-lymphocytes have led to the hypothesis that NAADP might act as a trigger by releasing enough Ca²⁺ to induce and/or sensitize the other two mechanisms to amplify its signal. This cross-talk means that cells might encode signals via increasing the three second messengers to different levels, instead of having the option to modulate just one messenger to different levels. The net outcome of this could be the possibility to use Ca²⁺ to specifically and unambiguously encode a higher number of intracellular messages.

At present, no extracellular message has been linked unequivocally with NAADP signaling. Nonetheless, the capacity of high concentrations of NAADP to block the release mechanism has been used experimentally to suggest that NAADP might be involved, among other functions, inolecystokinin-mediated signaling in pancreatic acinar cells, in insulin signaling in β-cells, and in the T-cell receptor/CD3 signaling.

Metabolism of NAADP

It has been shown that cADPR, a derivative of nicotinamide adenine dinucleotide (NAD), in which the nicotinamide has been cleaved and the terminal ribose is cyclized with the adenine group at the N1 position, can be synthesized by a subfamily of NAD⁺ glycohydrolases. Members of this family have been characterized in *Aplysia* and in mammalian systems. These enzymes are peculiar since they are able to catalyze both the cyclization and the degradation of cADPR. Surprisingly, in the presence of nicotinic acid, these enzymes are also capable of catalyzing a base-exchange reaction that replaces the nicotinamide on NADP with nicotinic acid to produce NAADP. Therefore, it is likely that these enzymes are central to calcium signaling, since they can catalyze the production of two signaling molecules with two distinct targets, as well as the degradation of one of these. For this mechanism to produce diversity, it could be hypothesized that the different reactions should be modulated differently by intracellular pathways. Recent evidence suggests that this might be the case. First, the base-exchange reaction seems to be favored over the cyclization in acidic conditions, although substantial amounts of NAADP are generated at physiological pH. Second, both the laboratories led by Lee and by Galione have separately shown that cyclic nucleotides can differentially regulate the production of cADPR and NAADP. In particular, in sea urchin eggs elevations of cAMP appear to favor NAADP production while elevations of

cGMP favor production of cADPR. Nonetheless, this could be due to either a differential modulation of the same enzyme or modulation of two separate enzymes. Among the enzymes described to date that can catalyze these reactions, the mammalian members, the most important of which is the lymphocyte antigen CD38, are membrane-bound ectoenzymes, with extracellular catalytic activity. Although there are some descriptions of CD38 present on intracellular membranes such as the nuclear envelope or the mitochondrion, it is likely that other members of this family will be described in the future that possess intracellular activity. Alternatively, the group led by De Flora has postulated a mechanism by which the extracellularly produced messengers can be internalized.

NAADP degradation has been shown to occur in both invertebrate and vertebrate cells. The mechanism by which this occurs is at present unknown, although it has been recently postulated that in mouse tissues a Ca²⁺-dependent phosphatase, via conversion to NAAD, might be involved in the termination of signaling by NAADP.

In most systems evaluated to date, NAADP induces Ca²⁺ release at low nanomolar concentrations, making its detection extremely difficult. It has recently been shown that sea urchin sperm contains micromolar levels of NAADP, together with a membrane-bound high-capacity enzyme for its synthesis. It is

likely that these observations will be extended to other systems with the characterization of more sensitive detection methods.

Intracellular Calcium Waves

J T Chun and L Santella, Stazione Zoologica Anton Dohrn, Villa Comunale, Napoli, Italy

© 2013 Elsevier Inc. All rights reserved.

Glossary

Action potential A momentary reversal in electrical potential across a plasma membrane, as of neurons, muscles, and fertilized eggs, that occurs when a cell has been activated by a stimulus.

Calcium release-activated calcium channel protein 1 (ORAI1) A calcium selective ion channel in the cell plasma membrane that is activated upon the depletion of endoplasmic reticulum (ER) calcium stores.

Glutamate receptors Specific receptors that bind to the most common neurotransmitter in the brain, L-glutamate. There are two broad categories of glutamate receptors: ionotropic receptors and metabotropic receptors. The ionotropic glutamate receptors are ligand-gated ion channels and are further subdivided based on their ligand

specificity: α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), kainite, and N-methyl-D-aspartate (NMDA) types. On the other hand, metabotropic glutamate receptors transmit the signals by the action of the coupled G-proteins.

Sarco/endoplasmic reticulum Ca^{2+} -ATPase (SERCA) pump An ion pump that transfers Ca^{2+} from the cytosol to the lumen of the sarcoplasmic or endoplasmic reticulum of the cell at the expense of ATP hydrolysis.

Stromal interaction molecule 1 (STIM1) A transmembrane protein enriched in the ER that functions as a sensor for the decrease of Ca^{2+} concentration in the ER lumen.

Synaptotagmin A family of membrane-trafficking proteins that function as calcium sensors and regulate neurotransmitter and hormone release.

Phenomena

The concept that Ca^{2+} ion transduces extracellular stimuli into intracellular reaction dates back to the seminal work by Sydney Ringer in 1883. He observed that an isolated heart can beat only when Ca^{2+} is present in the medium. The significance of this observation, confirmed and appreciated decades later, is that a simple substance such as Ca^{2+} can substitute the external stimuli to activate an intracellular process. Since the same external stimuli actually induce an increase of intracellular Ca^{2+} , Ca^{2+} must have worked as a second messenger. In addition to its role in muscle contraction, Ca^{2+} serves as an intracellular regulator of diverse cell activities such as fertilization, neurotransmission, exocytosis, endocytosis, cell division, and cell death, to name a few.

That Ca^{2+} is implicated in these processes has been demonstrated either by substituting Ca^{2+} ions in the media or by using specific chelators or pharmacological agents that respectively reduce or increase the intracellular Ca^{2+} levels. Furthermore, application of electrophysiological methods measuring the membrane potential and ion currents across the membrane made it possible to study Ca^{2+} influx or efflux, while a more recent development of fluorescent Ca^{2+} indicators and the imaging technology such as rapid scanning confocal microscopy or video fluorescence microscopy has provided spatiotemporal information on Ca^{2+} mobilization inside the cell. Thus, the wave of Ca^{2+} propagating inside a living cell was first visualized in the fertilized eggs of medaka (a freshwater fish) and sea urchins by the use of photoprotein called aequorin in the late 1970s. These cells were large enough (1 mm and 80 μm , respectively) to facilitate microinjection and the imaging procedure that provided relatively low spatiotemporal resolution at that time. However, with more recent development of fluorescent protein probes being targeted to specific organelles and the chelator-type sensitive Ca^{2+} indicators (Fura, Fluo, Indo,

Calcium Green, etc.), whose emission of fluorescence is greatly enhanced upon binding to free Ca^{2+} , the intracellular Ca^{2+} wave has been observed not only in excitable cells such as neurons and myocytes but also in a variety of cell types, including pancreatic acinar cells, astrocytes, hepatocytes, fibroblasts, endothelial cells, and embryonic cells in many different physiological contexts.

Fertilization exemplifies one of the most intense intracellular Ca^{2+} signalings, as both sperm and eggs are activated by the wavelike rises of intracellular Ca^{2+} . Owing to the exceptionally large cell size, intracellular Ca^{2+} waves have been best demonstrated in the fertilized eggs. In the eggs of all animal and plant species tested, fertilization is immediately accompanied by the generation of the Ca^{2+} wave that initiates at the sperm entry site and propagates through the cytoplasm. The fertilization Ca^{2+} wave can produce either single (echinoderms, amphibians, echinuran worms, and mollusks) or multiple peaks (mammals, ascidians, and polychaete worms), depending on the species. However, the physical characteristics of the fertilization Ca^{2+} wave are highly conserved, as the average speed of its propagation (2–10 $\mu\text{m s}^{-1}$) and the amplitude of the local Ca^{2+} rise (1–5 μM) at the wave front are estimated to be in the same order of magnitude across a wide spectrum of animal species ranging from sponges to mammals. Although Ca^{2+} can also enter the fertilized egg from the extracellular space, the major part of the Ca^{2+} rise in the cytoplasm is due to the release of the sequestered free Ca^{2+} from the intracellular stores such as the lumen of the endoplasmic reticulum (ER). The wavelike propagation of the Ca^{2+} signals in the cortex of the fertilized egg is essential for the postfertilization egg activation. In echinoderm (sea urchin and starfish) eggs, the Ca^{2+} waves precede the arrival of the surface wave of the egg activation which is characterized by the gradual elevation of the vitelline layer due to the Ca^{2+} -dependent exocytosis of cortical granules. This leads to the formation of the fertilization

envelope in echinoderm eggs, which may serve as a mechanical block against polyspermy (Figures 1 and 2).

Another clear example of intracellular Ca^{2+} wave has been demonstrated in the context of muscle contraction. The three types of muscles, that is, skeletal, cardiac, and smooth muscles, all utilize Ca^{2+} as a messenger that converts depolarization of the membrane potentials to the generation of contractile force. The common theme is that an increase of cytosolic Ca^{2+} is required for myosin-based sliding of actin filaments. In skeletal muscles, nerve endings of somatic motor neurons make neuromuscular junction in which nerve-released acetylcholine binds to nicotinic receptors on the muscle membrane and produce sufficiently large ($\Delta \sim 60$ mV) depolarization at the motor end plates to ensure generation of action potentials on the sarcolemmal (plasma) membrane of the muscle.

The plasma membrane of skeletal and heart ventricular myocytes has deep invaginations called transverse tubules (t-tubules) that convey action potentials toward the cell interior. Moreover, the t-tubular membrane is in close contact with terminal cisternae of the sarcoplasmic (endoplasmic) reticulum, forming diad or triad structures. The t-tubule membrane is studded with voltage-sensitive L-type Ca^{2+} channels called dihydropyridine (DHP) receptors which are thought to be physically linked to the ryanodine receptors (RyRs) on the sarcoplasmic reticulum. Hence, the arrival of action potentials on the myocyte membrane opens not only the DHP receptor channels but also the RyRs via protein–protein interaction or calcium-induced–calcium-release mechanism (CICR), respectively (see below). The liberated Ca^{2+} in cytosol then binds to troponin and dislocates it from the actin filaments inside

Figure 1 Propagation of the intracellular Ca^{2+} wave in the fertilized egg of starfish (*Astropecten aranciatus*) and the consequent elevation of the fertilization envelope. Mature eggs microinjected with fluorescent Ca^{2+} indicators were fertilized to monitor the changes of the cytosolic Ca^{2+} levels. (a) Transmission photomicrographs of a representative fertilized egg were superimposed with the corresponding fluorescent images of the Ca^{2+} indicator (green) at each time point. (b) Quantification of the intracellular Ca^{2+} levels in reference to the basal level. In less than a minute after the arrival of the fertilizing sperm at the jelly coat ($t = 0:00$, min:sec), a quick Ca^{2+} increase takes place in the cortex (cortical flash; arrow at 0:26), and a wave of Ca^{2+} is generated from the sperm interaction site (arrowhead) and traverses the entire cytoplasm of the egg. By the end of Ca^{2+} wave propagation, a thick wall of fertilization envelope is formed over the egg surface as a result of cortical granule exocytosis. Reproduced from figure 1 in Puppo A et al. (2008) Alteration of the cortical actin cytoskeleton deregulates Ca^{2+} signaling, monospermic fertilization, and sperm entry. *PLoS ONE* 3:e3588.

Figure 2 Propagation of the oscillating Ca^{2+} waves in the fertilized egg of ascidian (*Ciona intestinalis*). (a) Fluorescent images of instantaneous increments ($F_{\text{inst}} = [(F_t - F_{t-1})/F_{t-1}]$) of intracellular Ca^{2+} levels constituting the first two Ca^{2+} waves after fertilization. Note the cortical flash at 0:11 that was successfully visualized because of the use of the intact eggs with the chorion. After the generation of the first Ca^{2+} wave at the sperm interaction site, the following repetitive waves start from the nearby spots, but not exactly from the original spot. (b) Quantification of the intracellular Ca^{2+} levels in reference to the basal level.

sarcomere so that myosin can gain an access to exert a power stroke. In this way, the electric signal in the muscle fibers is rapidly converted to the Ca^{2+} signals to activate a contraction-relaxation cycle of the muscle. Since the propagation speed of the action potential could be on the order of a few m s^{-1} , the excitation-contraction coupling is an example of a very fast way of increasing intracellular Ca^{2+} levels.

The sheer propagation of intracellular Ca^{2+} waves in muscle cells has often been demonstrated either in dissected muscles or in cultured myocytes independent of the activities of innervating nerves. When exposed to hypertonic sucrose-Ringer solution, the frog skeletal muscle fibers display Ca^{2+} oscillation that originates from specific sites and propagates over a few hundred micrometers at the speed of $30\text{--}40\ \mu\text{m s}^{-1}$ and with the frequency of about 7 waves per minute. Once initiated, this wave is independent of extracellular Ca^{2+} but can be blocked by ryanodine, the agonist/antagonist of RyRs, implying that the intracellular wave is mediated by the internal Ca^{2+} stores. Similarly, myocytes from guinea pig ventricle have displayed submicromolar Ca^{2+} waves that rapidly propagate ($\sim 100\ \mu\text{m s}^{-1}$) down the longitudinal axis of the cell. Unlike ventricular myocytes, atrial myocytes lack t-tubules, and the main source for priming Ca^{2+} waves here is the large influx from the plasma membrane by voltage-gated calcium channels (VGCCs). The resulting Ca^{2+} sparklet diffuses and activates further Ca^{2+} release from RyRs on the sarcoplasmic reticulum through the CICR mechanism. Indeed, the cat atrial myocytes produce Ca^{2+} waves 70–100 ms after electrical stimulation, but blockade of RyRs with ryanodine restricts the Ca^{2+} increase mainly to the cell periphery. Reflecting the anatomical differences with respect to the presence of the t-tubule, the Ca^{2+} wave in rat atrial myocytes requires longer lag time (30 ms) for the Ca^{2+} level to rise in the entire cell than in ventricular myocytes, although the velocity of the Ca^{2+} wave itself is virtually the same ($>100\ \mu\text{m s}^{-1}$).

Mammalian smooth muscles are markedly different from skeletal and cardiac muscles. First of all, smooth muscles are not made of sarcomeres but are arranged in oblique bundles. Their structural organization is as diverse as their specialized functions in vascular, gastrointestinal, respiratory, ocular, urinary, and reproductive systems. Second, smooth muscles are associated with tropomyosin but lack troponin that binds Ca^{2+} and releases the inhibitory mechanism of sarcomere contraction seen in skeletal muscles. Inevitably, Ca^{2+} should initiate contraction of smooth muscles in a different way. Increased by both influx and the internal release from the sarcoplasmic reticulum, cytosolic Ca^{2+} binds to calmodulin and activates a host of proteins including the enzyme that phosphorylates myosin, for example, myosin light chain kinase. This cascade of change initiated by the Ca^{2+} signal eventually enhances myosin's adenosine triphosphatase (ATPase) activity and increases muscle contraction.

Ca^{2+} is instrumental in contraction of all smooth muscle cells, but the way intracellular Ca^{2+} level is increased and how it contributes to muscle contraction are widely variable in different cell types. Smooth muscle cells in the vascular system (blood flow) can exert prolonged tonic contraction, while other cells in bladder (micturation), uterus (labor contraction), and vas deference (ejaculation) require rapid and strong responses to the stimuli with a short period of excitation

(phasic contraction). The increase of cytosolic Ca^{2+} levels and the subsequent contraction of the smooth muscles are controlled not only by neurotransmitters but also by hormones and paracrine mechanisms. Hence, smooth muscle cells integrate multiple (sometimes contradictory) influences and produce a modulated response. For example, detrusor smooth muscle cells in the bladder display intrinsic capability of spontaneous contraction, but such endogenous contraction needs to be synchronized by the parasympathetic nerves in order to produce sufficient intravisceral pressure for micturation. During bladder emptying, the binding of neurotransmitters (acetylcholine and extracellular adenosine triphosphate (ATP)) increases the frequency of the action potentials. As each action potential is widely spread and is followed by contraction, the bladder now produces a concerted phasic contraction. This action potential and muscle contraction depend on Ca^{2+} influx, as they are prevented by inhibitors of L-type Ca^{2+} channels.

Most visceral smooth muscle cells surrounding internal organs (viscera), blood vessels, and intestinal tracts are electrically interconnected through gap junctions, which can rapidly spread action potentials to induce a unitary contraction of the entire sheets of tissues. For instance, the spontaneous Ca^{2+} transient generated in the smooth muscles of the guinea pig urinary bladder can traverse the muscle bundles as rapidly as $1.5\ \text{mm s}^{-1}$, but the propagation of this Ca^{2+} wave can be specifically disrupted by 18β -glycyrrhetic acid, a gap junction blocker. The propagation of action potentials and Ca^{2+} signals by gap junctions can thus be used as a highly efficient strategy to contract the whole tissue by using a few specialized pacemaker cells. For example, interstitial cells of Cajal are specialized smooth muscle cells of the gastrointestinal tract that generate periodic Ca^{2+} pulses and the consequent slow wave potentials to activate local population of smooth muscle cells. This slow wave potential is much more infrequent (3–12 waves per minute) than the myocardial pacemaker potentials (60–90 waves per minute). However, when the membrane depolarization surpasses the threshold, VGCC opens and the entering Ca^{2+} fires one or more action potentials. The spontaneous repetitive Ca^{2+} transients then travel through the myenteric region as a wave at the velocity of $2\ \text{mm s}^{-1}$ and activate the attached muscle fibers. The blockade of gap junctions disrupts the rhythmicity and synchronicity of the Ca^{2+} oscillations, while individual cells continue to pace independently with no reduction in the amplitude of the transients.

Intracellular Ca^{2+} increase has also been demonstrated in neurons, as it is associated with neuronal activities. In the context of excitation-secretion coupling, a large increase of cytosolic Ca^{2+} ($\sim 200\ \mu\text{M}$) was demonstrated at the synapse of squid giant axons. The firing of action potentials leads to rapid rise of this highly localized Ca^{2+} surge at the presynaptic terminals, and this Ca^{2+} increase is essential to the secretion of neurotransmitters. While squid giant axons represent a special type of axon that is formed by syncytial fusion of neurons to increase the axon diameter and electric signal conduction, similar excitation-secretion coupling involving Ca^{2+} increases also takes place in other ordinary neurons. Furthermore, intracellular Ca^{2+} can also be increased in postsynaptic neurons following neurotransmission, as has been demonstrated in a variety of cells including pyramidal neurons of the

hippocampus and neocortex, dopaminergic neurons of the midbrain, and Purkinje cells of cerebellum. In neocortical pyramidal neurons, repetitive electric stimulation at the apical dendritic shaft produces a sharp Ca^{2+} spike ($1\ \mu\text{M}$) that is followed by a larger but delayed (by 500 ms) Ca^{2+} wave ($\sim 5\ \mu\text{M}$). This latter Ca^{2+} wave (estimated $5\text{--}10\ \mu\text{m s}^{-1}$) propagates about $10\ \mu\text{m}$ in both directions and is sensitive to drugs blocking RyRs and inositol 1,4,5-trisphosphate (InsP_3) receptors (InsP_3Rs), suggesting that it is released from the intracellular stores. This slow but longer-lasting ($>1\ \text{s}$) Ca^{2+} release is not evocable in the peripheral regions beyond $150\ \mu\text{m}$ from the soma. Hence, the slow Ca^{2+} increase does not occur synchronously in all location of the cell but instead spreads as a wave over a restricted region. By contrast, the Ca^{2+} increase induced by back-propagating action potentials is much faster in response (2 ms) and propagates more than 1 mm from the soma and from the stimulation site, albeit smaller in amplitude ($<1\ \mu\text{M}$). Therefore, there are clearly distinct ways of delivering Ca^{2+} signals in neurons.

Intracellular Ca^{2+} waves were observed not only in neurons but also in astrocytes, the prevailing cell type in the brain. Filopodial extension of astrocytes envelops synaptic cleft that is occasionally flooded with neurotransmitters such as glutamate. Recent studies showed that astrocytes not only release glutamate but also propagate intracellular Ca^{2+} wave in response to extracellular glutamate or ATP. Although the exact physiological concentration of neurotransmitters in the synaptic cleft is hard to estimate, submicromolar level of glutamate and ATP can generate localized Ca^{2+} waves. At higher concentration ($10\text{--}100\ \mu\text{M}$) of glutamate, Ca^{2+} propagates not only within a single cell with a velocity of $20\ \mu\text{m s}^{-1}$ but also through adjacent cells with a slightly lowered velocity ($15\ \mu\text{m s}^{-1}$). This intercellular propagation of Ca^{2+} wave was observed to propagate nearly $770\ \mu\text{m}$ spanning more than 50 cells. The latter process is believed to be mediated through an electrically coupled syncytium, as blockers of gap junctions can inhibit the Ca^{2+} propagation. However, this type of intercellular Ca^{2+} signaling can also be mediated by extracellular ATP that serves as a diffusible messenger (Figure 3).

Similarly, a coordinated intracellular propagation of Ca^{2+} signals has been demonstrated in tracheal epithelial cells, where Ca^{2+} signaling plays a crucial role in maintaining mucociliary clearance. A mechanical distortion of the apical membrane of the tracheal epithelial cell generates a Ca^{2+} wave in the cell within 3 s, which then spreads to neighboring cells as far as $300\ \mu\text{m}$ with the velocity of $15\ \mu\text{m s}^{-1}$. The arrival of the oscillating Ca^{2+} waves then increases and sustains the ciliary beat frequency. As in astrocytes, this intercellular propagation of Ca^{2+} depends on gap junction and can also be induced by extracellular ATP that mediates autocrine or paracrine actions. Ca^{2+} waves characterized by mechanical induction and subsequent intracellular propagation via gap junctions and/or extracellular ATP have been actually reported in various mammalian cells including thymic epithelial cells ($6\text{--}10\ \mu\text{m s}^{-1}$), mast cells ($5\text{--}10\ \mu\text{m s}^{-1}$), prostate cancer cells ($15\ \mu\text{m s}^{-1}$), endothelial cells of arteries ($10\ \mu\text{m s}^{-1}$), retinal pigment epithelial cells ($10\text{--}30\ \mu\text{m s}^{-1}$), and the osteoblastic cell line ($10\ \mu\text{m s}^{-1}$).

The pancreas plays both endocrine and exocrine roles in the body of vertebrate animals. It not only releases hormones such

Figure 3 An example of intercellular propagation of Ca^{2+} waves in astrocytes following the stimulation of the co-cultured neurons. (a) Transmission photomicrographs of the areas confluent with astrocytes. (b) Fluorescent images of instantaneous increments of intracellular Ca^{2+} levels that propagate as a sweeping wave across the layer of astrocytes. Scale bar = $50\ \mu\text{m}$. as insulin, glucagon, and somatostatin (endocrine) but also excretes bicarbonate and digestive enzymes into the duct that drains to the lumen of the duodenum (exocrine). While bicarbonate is mainly provided by the cells forming the wall of the duct, the digestive enzymes are excreted by a specialized cluster of cells that resemble a lobe of berry (*acinus* in Latin) and are thus called acinar cells. This morphologically polarized cell generates and propagates intracellular Ca^{2+} wave when stimulated with acetylcholine (neurotransmitter) and cholecystokinin (peptide hormone). The wave displays agonist-specific oscillation patterns, presumably due to the distinct distribution of the receptors having different physical characteristics. In general, acetylcholine evokes sinusoidal oscillations with repetitive Ca^{2+} spikes, whereas cholecystokinin produces short-lasting (2 s) Ca^{2+} spikes with long intervals. The latter agonist produces Ca^{2+} spikes that are followed by a global and long-lasting (30 s) Ca^{2+} waves much more often than acetylcholine does. The velocity of the Ca^{2+} wave generated by acetylcholine is increased with the increasing agonist concentration and could reach nearly $100\ \mu\text{m s}^{-1}$, while the observed maximal velocity of the cholecystokinin-evoked Ca^{2+} wave is about $60\ \mu\text{m s}^{-1}$. Similar to these oscillating patterns of Ca^{2+} waves, patch pipette-injected InsP_3 produces repetitive Ca^{2+} spikes whose amplitude and frequencies can be modulated by the agonist concentration. In most cases, these waves have been observed to travel in an apical (lumen side) to basal direction. The Ca^{2+}

waves in pancreatic acinar cells are instrumental both in exocytosis of enzymes and in the activation of Cl^- channels to extrude the ions to the lumen.

An earlier example of nonexcitable cells propagating or oscillating Ca^{2+} waves was found in isolated hepatocytes of rats. When exposed to adrenergic agonists and vasopressin, these cells respond with oscillatory Ca^{2+} waves that initiate always at the specific subplasmalemmal region and propagate to the restricted adjacent subcellular regions with the speed of $20\text{--}25\ \mu\text{m s}^{-1}$. The dose of hormones does not affect the speed and amplitude (about $700\ \text{nM}$) of the Ca^{2+} wave but alters the frequency of the Ca^{2+} oscillations ($0.5\text{--}0.9$ peaks per minute).

Finally, it should be noted that different types of Ca^{2+} waves have also been observed whose propagation velocities are at least one or two orders of magnitude lower than those of the aforementioned examples. These slow waves are more easily observed along the cleavage furrows of the cells during cytokinesis in early embryos at the cleavage stage. During the first mitosis of *Xenopus* zygote, a slow-moving Ca^{2+} wave ($3\ \mu\text{m s}^{-1}$) travels along the cleavage furrows but not in the direction orthogonal to it. In medaka fish eggs, the corresponding wave apparently travels even more slowly ($0.5\ \mu\text{m s}^{-1}$). Since the cleavage furrow is formed and operated by extremely thin actinomyosin band (contractile ring), the Ca^{2+} wave may be related to the generation of the mechanical force required for cell cleavage. In addition, it may induce exocytosis to provide increased amount of plasma membrane to support cytokinesis.

Mechanisms of the Ca^{2+} Waves

The concerted increase of intracellular Ca^{2+} concentration has been often referred to as a wave in a sense that it is mobilized or periodically alternates its amplitude in space and time. However, it is rather an intuitive definition. Unlike a ripple that propagates over the water surface or the electromagnetic radiation that travels in free space, an intracellular Ca^{2+} wave is generated and propagated inside a living cell, traveling through a highly heterogeneous medium of cytoplasm that is crowded with organelles, the cytoskeleton, and numerous particles like proteins that may participate in shaping the Ca^{2+} wave by buffering or regenerating the wave. Thus, its description in mathematical terms is not a straightforward task. Despite the numerous unpredictable variables, however, several calcium formulas have been proposed to account for the particular patterns of Ca^{2+} mobilization in a given cell such as a *Xenopus* oocyte. Though contributions from minor variables are inevitably neglected, simulation of the wave by these models often approximates the experimental observation. While making a unifying model that perfectly fits all cells would be simply impossible, one could consider several basic strategies that a cell may use to propagate a Ca^{2+} wave.

First of all, Ca^{2+} can be suddenly brought from outside of the cell. To maintain cytosolic Ca^{2+} at low concentration, cells continuously pump out Ca^{2+} into extracellular space, but the trend could be reversed upon certain external cues. Depolarization of the cell membrane can quickly activate two Ca^{2+} influx pathways that either activate VGCC or reverse the action mode of $\text{Na}^+\text{--}\text{Ca}^{2+}$ exchangers on the plasma membrane.

Since depolarization is the initial cause of action potentials, Ca^{2+} influx is often associated with the propagation of action potentials, which could be as fast as $20\ \text{m s}^{-1}$ (estimation in squid giant axons). Hence, Ca^{2+} influx can provide an extremely fast way of sending Ca^{2+} signals to the other side of the cell, which is remote from the site of stimulus. However, the Ca^{2+} imported in this way usually does not propagate deep into the cytoplasm albeit its high lateral speed. One good example of this extremely fast mode of increasing Ca^{2+} concentration inside a cell is found in the fertilized eggs of echinoderms. The physical contact of the fertilizing sperm induces the depolarization of the egg membrane potential, and this immediately leads to a rise of the Ca^{2+} level in the tight subplasmalemmal regions of the entire egg surface. The rise and fall of the Ca^{2+} signal is so fast that it appears almost synchronized and is thus referred to as a cortical flash. Likewise, wiring myofibrils with t-tubules serves as a mechanism to expedite the Ca^{2+} response and synchronize the muscle contraction, although the speed of the Ca^{2+} signal itself is impeded by the diffusion step before reaching the downstream targets. In neurons, Ca^{2+} entry can also take place through ligand-gated channels such as *N*-methyl-D-aspartate (NMDA)-type glutamate receptors, which are selectively localized in dendritic spines. Whereas the Ca^{2+} influx through VGCC is fast but too short-lived to reach a high concentration, the highly localized Ca^{2+} transients fluxed through NMDA receptor last longer and thus exceed more than $1\ \mu\text{M}$ due to the long open time and the small volume of dendritic spines. On the other hand, Ca^{2+} can also enter through Ca^{2+} -permeable α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA) channels, which are localized in aspiny dendrites. Hence, Ca^{2+} ions have different physiological meanings depending on how they have entered the cell.

Intuitively, the most basic element of the intracellular Ca^{2+} wave would be diffusion. Once liberated from the mouth of ion channels, Ca^{2+} is free to diffuse to the areas of lower concentration until the dynamic equilibrium is reached. The speed of diffusion down the concentration gradient is proportional to the concentration difference between the two spots, dependent on temperature, and is inversely proportional to the square of the distance. Hence, a drop of ink dripped into a glass of water will diffuse fast in the beginning, but the speed will gradually diminish. If the propagation of Ca^{2+} in cells is solely based on diffusion, one would predict that the amplitude and the speed of the Ca^{2+} transient will dwindle as the wave propagates. However, the Ca^{2+} waves propagating in fertilized eggs and other cells can travel long distances from the origin without losing the velocity and the amplitude of the wave fronts. Hence, besides diffusion, the intracellular Ca^{2+} wave must propagate by some kind of autocatalytic reaction that replenishes the signal and facilitates its propagation.

In this regard, cytoplasm can be considered an excitable medium where the wave is amplified in the propagating field before being diminished. The cytoplasm is packed with extensive network of endoplasmic (or sarcoplasmic) reticulum that serves as the major store of Ca^{2+} inside the cell. Through SERCA pumps, Ca^{2+} is continuously pumped from cytosol into these organelles to be loosely ($K_d=0.5\text{--}2\ \text{mM}$) bound to the storage proteins inside the lumen. As a result, Ca^{2+} in lumen may reach $>1\ \text{mM}$, and the concentration of free Ca^{2+}

is at least 100 times higher than that in cytosol ($0.1\text{--}1\text{ }\mu\text{M}$). Hence, the luminal Ca^{2+} is ready to diffuse out whenever the ion channels are open on the ER membrane. The important aspect is that these ion channels (InsP₃Rs, for example) are rapidly (within $10\text{--}50\text{ ms}$) activated by Ca^{2+} itself, once the ion reaches a threshold level ($0.2\text{--}0.4\text{ }\mu\text{M}$). This cooperative positive feedback provides an essential mechanism by which a local increase of Ca^{2+} can ignite further release of Ca^{2+} ions from the nearby InsP₃Rs. As the local Ca^{2+} concentration exceeds a certain limit ($>1\text{ }\mu\text{M}$), the ion channels slowly ($1\text{--}10\text{ s}$) close down, passing the torch of Ca^{2+} signals to the next InsP₃Rs in line. This spatiotemporally coordinated opening of several channels by Ca^{2+} ion is thus termed CICR and may serve as a fundamental mechanism by which to propagate Ca^{2+} waves inside the cell without causing excessive elevation of cytosolic Ca^{2+} concentration. CICR was initially discovered as a mechanism to mobilize Ca^{2+} waves through RyRs, which is thought to be the major mediator of CICR in animal cells. As mentioned above, an antagonist (ryanodine) of this receptor blocks propagation of the Ca^{2+} waves in the frog muscles, but other cells may employ InsP₃Rs for CICR.

Besides Ca^{2+} , physiological gating agents (ligands) can also activate RyRs and InsP₃Rs. Whereas the question of cyclic ADP ribose (cADPr) being a true ligand or a modulator of RyRs may be disputable because of its delayed effect on the receptor ion channel activities, InsP₃ binds to its receptor as a ligand and directly opens the channel or allosterically modulates its sensitivity to Ca^{2+} inhibition so that the open probability of the channel is increased. Since the enzyme that hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to produce InsP₃ and diacylglycerol (DAG), that is, phospholipase C (PLC), is activated by a Ca^{2+} rise itself, this three-way causal relationship among InsP₃, Ca^{2+} , and PLC constitutes another important positive feedback loop that sustains the regenerative Ca^{2+} waves on a slower timescale of $1\text{--}2\text{ s}$. Hence, the latter mechanism termed InsP₃- Ca^{2+} coupling (ICC) could set the tone to the slower but more global Ca^{2+} response of cells.

The Ca^{2+} -releasing second messenger InsP₃ has another crucial added value, that is, InsP₃ is readily diffusible inside the cell. Whereas an individual Ca^{2+} ion does not diffuse much inside the cell due to the hundreds of binding molecules, InsP₃ is relatively free from these buffering effects. Indeed, experimental data from the cytosol of *Xenopus* oocytes estimated that the diffusion coefficient of InsP₃ ($D = 280\text{ }\mu\text{m}^2\text{ s}^{-1}$) far exceeds that of Ca^{2+} ions ($D = 13\text{ }\mu\text{m}^2\text{ s}^{-1}$ for 90 nM Ca^{2+} in cytosol). Hence, InsP₃ can diffuse $5\text{--}30$ times faster than Ca^{2+} , and its function as a mobile igniter of intracellular Ca^{2+} signaling has been clearly demonstrated in astrocytes where InsP₃ diffuses through gap junctions and releases Ca^{2+} in an array of neighboring cells. Since InsP₃ synthesis takes place in the plasma membrane, while the major internal Ca^{2+} store is the ER, the mobility InsP₃ entitles it as a traveling messenger that bridges the gap between the two sites.

Ca^{2+} transients in cells have been referred to as puff (a group of InsP₃Rs), spark (cardiac RyRs), sparklet (VGCC), and so on, depending on the nature of the elementary releasing source. For these elementary Ca^{2+} transients to develop into a traveling wave, they should be sustained by CICR. The liberated Ca^{2+} ions diffuse to the vicinal channels (RyRs and

InsP₃Rs) on the ER and make them release more Ca^{2+} ions, which diffuse further and open more channels to continue a chain reaction of regenerative Ca^{2+} release from the internal stores. As a result, Ca^{2+} propagates like toppling dominos. While RyRs underlie CICR in skeletal muscles, InsP₃Rs also contribute to CICR in many other cell types through its dual dependency on InsP₃ and Ca^{2+} . Since Ca^{2+} has limited capability of diffusion in cells, it is critical that the discrete Ca^{2+} release sites should be spaced at short intervals. This spacing of ion channels and the presence of faster moving second messenger would profoundly affect the spreading range and speed of the Ca^{2+} wave. Indeed, at low InsP₃ concentration, the release sites separated more than $6\text{ }\mu\text{m}$ tend to fail in propagating a Ca^{2+} wave. In this regard, it is worth noting that the t-tubules of muscle cells are aligned in regular arrays at $2\text{-}\mu\text{m}$ intervals and that InsP₃Rs are tightly localized at the luminal side of the pancreatic acinar cells where Ca^{2+} signals start to propagate. Likewise, during meiotic maturation of *Xenopus* eggs, InsP₃Rs on the ER become more clustered to boost the Ca^{2+} release and wave propagation.

Whereas the spatial propagation of Ca^{2+} waves has been more easily demonstrated in large cells such as oocytes, the oscillatory aspect of the Ca^{2+} waves was recognized in small cells where the length of the wave front is comparable to the cell size. In principle, periodic opening of Ca^{2+} channels in the plasma membrane can be sustained by CICR or Ca^{2+} -dependent synthesis of InsP₃ to provide a cell-wide propagation of Ca^{2+} waves. If this is timely coordinated with depletion of the internal stores or with the mechanisms that sequester or terminate Ca^{2+} transients, a Ca^{2+} oscillation can take place. Indeed, CICR can be terminated by Ca^{2+} -dependent inhibition of InsP₃Rs, and Ca^{2+} can also be quickly sequestered by mitochondria that cooperate with the ER by serving as a temporary Ca^{2+} reservoir. Thus, the interval between transients may be decided by how quickly the InsP₃-sensitive internal stores can be recharged. Like a standing wave or a blinking semaphore, this type of Ca^{2+} oscillation often contributes to biorhythmicity, for example, the way that Ca^{2+} influx contributes to creating action potentials has been well described in cardiac muscles. As in skeletal muscles, contraction of the heart muscle is initiated by action potentials. Uniquely, however, this action potential is spontaneously generated by pacemaker cells and spread into contractile cells via gap junctions, while the neurotransmitters from sympathetic and parasympathetic nerves only modulate the pacemaker rate. In the latter (myocardial contractile) cells, Na^+ -dependent membrane depolarization slowly opens VGCC, and thus the depolarized phase is much prolonged (over 200 ms , forming a plateau) to squeeze out blood in a more efficient way. On the other hand, myocardial autorhythmic (pacemaker) cells have innately unstable resting membrane potential (pacemaker potential) due to the presence of special ion channels that conduct so-called funny current, which is made of both Na^+ and K^+ currents. As Na^+ influx exceeds K^+ efflux, slow depolarization occurs. This begins to open VGCC to let in Ca^{2+} , while funny channels gradually close. Thus, it is mainly the Ca^{2+} current (not Na^+ current) that pushes the membrane potential above the threshold and causes action potentials. In these ways, Ca^{2+} is involved in shaping the characteristic trajectories of action potentials in both cardiac cell types.

Whether taking place spontaneously or induced by external stimuli, the intracellular Ca^{2+} waves usually display unique patterns characteristic of the cell type. These signature Ca^{2+} responses are shaped by the concerted action of ion channels and the mechanisms that amplify or absorb the Ca^{2+} signal. Hence, precise subcellular localization of the specific proteins being involved in these processes would be the key parameter deciding the pattern of the Ca^{2+} response. For example, neurotransmitter glutamate can either directly bind to the receptors that conduct Ca^{2+} influx (NMDA receptor) or indirectly induce Ca^{2+} influx through VGCC by depolarizing the membrane potential. Furthermore, the same glutamate can also bind to the metabotropic receptors, which activate G-proteins and ultimately release Ca^{2+} from internal stores by stimulating PLC activity and InsP_3 production. Depending on the receptor types and the downstream G-protein subunits that activate different PLC subtypes, the same glutamate produces either single Ca^{2+} transient or an oscillatory Ca^{2+} response. Obviously, the spatiotemporal dynamics of these Ca^{2+} responses from the same agonist would be widely variable depending on the pathways.

It has been demonstrated that the major part of Ca^{2+} signals in fertilized eggs comes from internal stores. However, small cells depend more on external Ca^{2+} . In cells with relatively small capacity for intracellular Ca^{2+} storage (e.g., lymphocytes), depletion of the Ca^{2+} stores in the ER is sensed by the Ca^{2+} -binding protein STIM1 that forms a Ca^{2+} channel complex with ORAI1, and it leads to Ca^{2+} entry from the extracellular space. This slow (<100 s) but sustained store-operated Ca^{2+} (SOC) entry is the major pathway for Ca^{2+} influx in nonexcitable cells and provides a prolonged intracellular Ca^{2+} increase that may be used for slow cell responses such as changes of gene expression. Hence, cells have diverse repertoire of increasing and mobilizing intracellular Ca^{2+} , and the spatiotemporal profiles of the resulting Ca^{2+} waves are as diverse.

Physiological Significance of the Ca^{2+} Waves

Why does a Ca^{2+} signal carry such a specific pattern of wave propagation or oscillation? As an answer, it is generally conceived that the physiological meaning of external stimuli is often encoded in the magnitude, frequency, duration, and spatial organization of the Ca^{2+} signals. As mentioned earlier, the concentration of hormone is reflected by the frequency of Ca^{2+} oscillations in hepatocytes. For another example, the Ca^{2+} concentration inside the proximal dendrites of pyramidal neurons is quickly elevated to a certain level by a train of action potentials, and here again the amplitude of the Ca^{2+} level and its fluctuation frequency at the steady state are proportional to the frequency of the action potential. The physiological significance of the amplitude and frequency of Ca^{2+} transients has been demonstrated in neurites and growth cones. Whereas a burst of Ca^{2+} (~1 μM) virtually stops neurite elongation and growth cone motility, a more moderate physiological Ca^{2+} transients modulate both neurite outgrowth and path-finding activities of growth cones in a frequency-dependent manner. Hence, fine-tuning of Ca^{2+} transients has a fundamental effect on cell activity.

To produce a specific physiological response from a particular Ca^{2+} signal, the specific spatiotemporal pattern of the

Ca^{2+} profile has to be translated to a biochemical language. In cells, deciphering these codes is usually done by Ca^{2+} -binding proteins having a wide spectrum of binding affinity toward Ca^{2+} . For a protein such as calmodulin that has slow kinetics of Ca^{2+} binding, a Ca^{2+} transient decaying too fast would not be recognized at all, while it may be audible to certain other proteins that are more Ca^{2+} sensitive. On the other hand, a prolonged exposure to Ca^{2+} would activate multiple effectors, some of which might be even toxic to the cell. In this regard, delivering Ca^{2+} signals by oscillation might serve as a way to activate some exquisite effectors having slow Ca^{2+} -binding kinetics without causing such a deleterious effect. Thus, with the arrival of each repetitive Ca^{2+} spike, calmodulin would have more probability to bind Ca^{2+} and activate kinases and other specific targets. Discerning Ca^{2+} signals in one way or another would be utterly important because Ca^{2+} does so many diverse things in a cell that may be even contradictory sometimes. cAMP-response element-binding protein (CREB), a transcription factor implicated in learning and memory, is affected by Ca^{2+} since it is a substrate of Ca^{2+} /calmodulin-dependent kinases. Interestingly, CREB is activated only by Ca^{2+} pulses of certain temporal patterns (e.g., 1.8 s bursts separated by 1 min or 9 s bursts separated by 5 min). As Ca^{2+} can stimulate phosphatases as well, the temporal pattern of the Ca^{2+} signal might work as a specific code to phosphorylate and thereby activate CREB in the face of a counteracting pathway that dephosphorylates it.

The Ca^{2+} wave traveling from one point to another is a reasonably fast way of intracellular communication. The arrival of a fertilizing spermatozoon has to be heralded to the other parts of the egg so that it can start to coordinate the subsequent cell-wide changes such as wavelike exocytosis and rearrangement of the actin cytoskeleton. The Ca^{2+} surge in the fertilized eggs activates Ca^{2+} /calmodulin-dependent kinases and calcineurin, launching cascades of fine-tuning phosphorylation events that lead to cell-cycle progress and proper embryonic development. Hence, the changes in intracellular Ca^{2+} concentration can be converted to other forms of signaling in cells. The Ca^{2+} wave can even go beyond the cell boundary through gap junctions, as was exemplified in astrocytes. The velocity of intracellular Ca^{2+} waves could vary several orders of magnitude depending on the underlying mechanisms. Ca^{2+} signaling associated with action potentials and membrane depolarization provides the fastest method of delivering Ca^{2+} to the remote but superficial subcellular domains. On the other hand, the mechanism based on CICR promotes further progression of the Ca^{2+} waves into the deeper cytoplasmic territories.

Ironically, however, the most fundamental character of Ca^{2+} as a second messenger might lie in the fact that Ca^{2+} does not diffuse well inside a cell. In a typical cell with 300- μM binding protein concentration, it is estimated that an average Ca^{2+} ion migrates no further than 0.1–0.5 μm , lasting only about 50 μs before encountering a binding protein. As a substance, Ca^{2+} is an extremely localized second messenger despite the wave propagation. Owing to the tendency of low diffusion, the concentration of Ca^{2+} at the mouth of ion channels reaches over 100 μM , but the radius of its effect range is limited to merely 0.1 μm for 30 μs . Though spatially restricted, this signal is strong enough to activate proteins with low Ca^{2+} affinities such as synaptotagmin at the nerve

terminals or the vicinal ion channels responding to Ca^{2+} . The Ca^{2+} ions may diffuse further from the sphere of the primary impact, but would become low in concentration and be able to activate only those proteins having relatively higher Ca^{2+} affinities. Hence, how and where the Ca^{2+} puff was generated in a cell, and what target molecules were present in that micro- or nano-domain, would decide the physiological consequence of the Ca^{2+} wave. In this regard, the Ca^{2+} release machinery and the downstream effectors need to be strategically distributed in the proper subcellular microdomains in order to carry out the intended action.

Concluding Remarks

As was briefly reviewed in this article, signaling through a local or cell-wide increase of intracellular Ca^{2+} concentration has been observed in a wide variety of cells. Several molecular mechanisms explaining the phenomena of Ca^{2+} influx from the extracellular space and the efflux from the internal stores have been postulated mainly based on voltage-gated and ligand-gated Ca^{2+} channels. In parallel to the identification of ion channels, a number of agonists and second messengers that regulate the activity of the ion channels have been identified and characterized. Interestingly, molecules that initially appeared as simple metabolites such as InsP_3 , cADPr, and nicotinic acid adenine dinucleotide phosphate (NAADP) turned out to be diffusible second messengers that release Ca^{2+} from internal stores. While cADPr regulates the channel activity of RyRs and thereby contributes to the Ca^{2+} wave, NAADP is known to release Ca^{2+} from a different kind of internal store or from extracellular space. The NAADP-dependent Ca^{2+} signaling mechanism is not sensitized by Ca^{2+} , but the Ca^{2+} ions released from this route can still induce CICR from RyRs and InsP_3 Rs. Hence, it bears emphasis that any mechanism that causes Ca^{2+} influx or efflux counts in making an intracellular Ca^{2+} wave.

With no doubt, many things still remain to be learned about the generation and propagation of intracellular Ca^{2+} waves. Recently, novel classes of ion channels that are gated by mechanical stretch have been reported, but not yet characterized in great detail. Implying a potential involvement of such an intriguing mechanism in intracellular Ca^{2+} signaling, it has been demonstrated that mechanically stimulated myocytes produce Ca^{2+} influx that evolves into a wave and propagates even to the adjacent cells through gap junctions. On other occasions, it was also suggested that stretch-activated ion channels might be accountable for a certain class of Ca^{2+} waves whose velocity does not fall into the typical range that can be explained by VGCC or CICR mechanisms. Adding more interest to the topic, it has been suggested that the actin cytoskeleton might be able to modulate ion channel activities and intracellular Ca^{2+} signaling. In support of the idea, it has been reported that InsP_3 Rs are linked to actin filaments in mammalian cells and that the amplitude and the kinetics of Ca^{2+} rises in starfish eggs are modulated by structural alteration of the actin cytoskeleton. Being highly concentrated in cells ($>100 \mu\text{M}$) and organized as a dense meshwork subjacent to the plasma membrane, the actin filaments not only serve as a mechanical barrier for Ca^{2+} diffusion but might also modulate the activity of mechanosensitive ion channels in the vicinity. Furthermore, in a more radical view, it has also been suggested that actin tread-milling

could be used as a backup mechanism to temporarily store and release Ca^{2+} in a certain circumstance. Actin may bind substantial amount of Ca^{2+} when the local concentration of Ca^{2+} becomes high enough to be comparable with Mg^{2+} (near the mouth of ion channels). Once the Ca^{2+} -bound actin is incorporated into actin filaments, the Ca^{2+} -binding site is tucked in the groove of the F-actin helix, and thereby Ca^{2+} is protected from dissociation. While this process of actin polymerization can thus serve as a way to store Ca^{2+} , depolymerization of the microfilaments reverses the process and releases Ca^{2+} . Since an increase of Ca^{2+} can activate actin-binding proteins such as gelsolin that sever actin filaments, a wave of actin depolymerization, once started, might lead to the release of more Ca^{2+} and further depolymerization of actin. Hence, if Ca^{2+} release and actin depolymerization can form a positive loop similar to what we saw in RyRs and InsP_3 Rs, in theory, such a mechanism might also contribute to CICR in a cell.

Glossary

Gating The intrinsic regulatory process through which ion channels are opened and closed by conformational changes of the ion channel protein.

Ion channel A transmembrane protein that forms a pore through which ions move down their electrochemical gradients into or out of cells or intracellular organelles.

Rectifying An ion channel in which ion flow is favored in one direction, for example, inwardly rectifying potassium channels that conduct potassium ions inward more readily than outward, even though outward potassium movement is the physiologically relevant direction.

Voltage-gated channels Ion channels whose gating is regulated by changes in transmembrane voltage.

Electrical signals control contraction of muscle, secretion of hormones, sensation of the environment, processing of information in the brain, and output from the brain to peripheral tissues. In excitable cells, electrical signals also have an important influence on intracellular metabolism and signal transduction, gene expression, protein synthesis and targeting, and protein degradation. In all these contexts, electrical signals are conducted by members of the ion channel protein superfamily, a set of more than 140 structurally related pore-forming proteins. In addition, members of this protein family are crucial in maintaining ion homeostasis in the kidney and in many different cell types, and they also participate in calcium-signaling pathways in nonexcitable cells. In this article, the founding members of each family of ion channel proteins that are structurally related to the voltage-gated ion channels are introduced, and an overview of their structure, function, and physiological roles is presented. References are made to one or two recent review articles on each channel family to provide a broad introduction to the literature.

Voltage-Gated Sodium and Calcium Channels

The founding members of this superfamily in terms of its discovery as a separate protein are the voltage-gated sodium channels. These channels are specialized for electrical signaling and are responsible for the rapid influx of sodium ions that underlies the rising phase of the action potential in nerve, muscle, and endocrine cells. Neurotoxin labeling, purification, and functional reconstitution showed that sodium channels from mammalian brain contain voltage-sensing and pore-forming modules in a single protein complex of one principal α -subunit of 220–260 kDa and one or two auxiliary β -subunits of 36 kDa. The α -subunits of sodium channels contain four homologous domains, each containing six hydrophobic transmembrane segments. A membrane-reentrant loop between the fifth and sixth (S5 and S6) transmembrane segments forms the narrow extracellular end of the pore while the S6 segments form the intracellular end (Figure 1, red). The pore is formed in the center of a pseudosymmetric array of the four domains, and a single α -subunit containing four domains is able to receive voltage signals and activate its intrinsic pore. The channel responds to voltage by virtue of its S4 segments (Figure 1, green), which

contain repeated motifs of a positively charged amino acid residue followed by two hydrophobic residues, and move outward under the influence of the membrane electric field to initiate a conformational change that opens the pore. Drugs that block the pore of sodium channels are important as local anesthetics, antiarrhythmic drugs, and antiepileptic drugs. The four β -subunits consist of an amino-terminal extracellular immunoglobulin-like domain, a single transmembrane segment, and a short intracellular segment. They both modulate the gating of the α -subunits and serve as cell adhesion molecules by interaction with extracellular matrix, membrane, and cytoskeletal proteins. Nine voltage-gated sodium channel α -subunits, designated $\text{Na}_v1.1$ – 1.9 , have been functionally characterized. They comprise a single family of proteins with greater than 70% amino acid sequence identity in their transmembrane segments. One additional related α -subunit, which defines a second subfamily, $\text{Na}_v2.1$, is known but is apparently not voltage gated.

Voltage-gated calcium channels are the key signal transducers of electrical signaling, converting depolarization of the cell membrane to an influx of calcium ions that initiates contraction, secretion, neurotransmission, and other intracellular regulatory events. Skeletal muscle calcium channels first identified by drug labeling, purification, and functional reconstitution have a principal $\alpha1$ -subunit of 212–250 kDa, which is similar to the sodium channel α -subunit but is associated with auxiliary $\alpha2\delta$ -, β -, and γ -subunits that are unrelated to the sodium channel auxiliary subunits. Complementary DNA (cDNA) cloning and sequencing showed that the $\alpha1$ -subunit of calcium channels is analogous to the sodium channel α -subunits in structural organization (Figure 1) and is 25% identical in amino acid sequence in the transmembrane regions. As for the sodium channel α -subunit, the calcium channel $\alpha1$ -subunit is sufficient to form a voltage-gated calcium-selective pore by itself. Ten functional calcium channel $\alpha1$ -subunits are known in vertebrates, and they fall into three subfamilies that differ in function and regulation. The Ca_v1 family ($\text{Ca}_v1.1$ – 1.4) conducts L-type calcium currents that initiate contraction, endocrine secretion, and synaptic transmission at the specialized ribbon synapses involved in sensory input in the eye and ear. L-type calcium currents are also important regulators of gene expression and other intracellular processes. Blockers of $\text{Ca}_v1.2$ channels are important in the therapy of cardiovascular diseases, including hypertension, cardiac arrhythmia, and angina

Figure 1 The voltage-gated ion channel protein family. The different members of the ion channel protein family structurally related to the voltage-gated ion channels are illustrated as transmembrane folding diagrams in which cylinders represent probable transmembrane α -helices. Red, S5–S6 pore-forming segments; green, S4 voltage sensor; yellow, S1–S3 transmembrane segments; R, regulatory domain that binds intracellular second messengers. The numbers of family members in the human genome are given in parentheses.

pectoris. The Ca_v2 family of calcium channels ($\text{Ca}_v2.1$ – 2.3) conducts N-, P/Q-, and R-type calcium currents that initiate fast synaptic transmission at synapses in the central and peripheral nervous systems and are blocked specifically by peptide neurotoxins from spider and cone snail venoms. The Ca_v3 family of calcium channels ($\text{Ca}_v3.1$ – 3.3) conducts T-type calcium currents that are important for repetitive action potential firing of neurons in the brain and in the pacemaker cells of the sino-atrial node in the heart. The functional and regulatory properties and protein–protein interactions of these channels are adapted to their different roles in electrical signaling and cellular signal transduction.

Voltage-Gated Potassium Channels

Voltage-gated potassium channels are activated by depolarization, and the outward movement of potassium ions through them repolarizes the membrane potential to end action potentials, hyperpolarizes the membrane potential immediately following action potentials, and plays a key role in setting the resting membrane potential. In this way, potassium channels control electrical signaling and regulate ion flux and calcium transients in nonexcitable cells. The first voltage-gated potassium channels were cloned from *Drosophila* based on a mutation that causes the *Shaker* phenotype. They are composed of four transmembrane subunits, each of which is analogous to a single domain of the principal subunits of sodium or calcium channels (Figure 1). The voltage-gated potassium channels are remarkable for their diversity. They include 40 different channels that are classified into 12 distinct groups based on their amino acid sequence homology (K_v1 – K_v12). These α -subunits can assemble into homo- and heterotetramers within each subfamily, leading to a wide diversity of different channel complexes. The K_v1 channels also associate with $\text{K}_v\beta$ -subunits, which are intracellular proteins. The K_v4 subunits associate

with KChIPs, intracellular calmodulin-like calcium-binding proteins that regulate channel gating. Some of the K_v7 and K_v11 α -subunits associate with single membrane-spanning subunits (minK, MiRP1, and MiRP2), which regulate their gating properties. The diversity of potassium channels allows neurons and other excitable cells to precisely tune their electrical signaling properties by expression of different combinations of potassium channel subunits.

Second-Messenger-Gated and Sensory Ion Channels

In addition to the voltage-gated sodium, calcium, and potassium channels, the voltage-gated ion channel family includes additional members that are gated by a combination of voltage and binding of second messengers, including calcium, cyclic nucleotides, and lipid messengers. These channels have six transmembrane segments and a generally similar structure to voltage-gated potassium channels, but contain in addition a regulatory domain attached at their carboxy terminus.

Calcium-activated potassium channels ($\text{K}_{\text{Ca}}1$ – 3) have an ion channel domain attached to an intracellular calcium-dependent regulatory domain in their C-terminus. They are activated by a combination of depolarization and binding of calcium ions. For the $\text{K}_{\text{Ca}}1$ channels, calcium binding to a regulatory domain in the C-terminus (R, Figure 1) enhances activation of the channels by depolarization, resulting in synergistic gating of channel activity by voltage and intracellular calcium concentration. $\text{K}_{\text{Ca}}1$ channels have an extra transmembrane segment at the N-terminus (S0) and associate with $\text{K}_{\text{Ca}}\beta$ -subunits, which are 2-TM intrinsic membrane proteins. For $\text{K}_{\text{Ca}}2$ or $\text{K}_{\text{Ca}}3$ channels, calcium binds to a constitutively associated calmodulin molecule bound to the C-terminal regulatory domain and activates the channels without a voltage stimulus. The $\text{K}_{\text{Ca}}1$ – 3 channels serve to repolarize excitable cells following single-action potentials or trains of action

potentials, during which calcium entry increases the cytosolic calcium levels and activates them. One of their prominent roles is to define the length of action potential trains in neurons by activating in response to calcium influx through voltage-gated calcium channels and thereby repolarizing and hyperpolarizing the cell. Similarly, in smooth muscle cells they hyperpolarize the membrane and relax the smooth muscle. The K_{Ca4} and K_{Ca5} channels resemble K_{Ca1} channels in structure, but are not regulated by intracellular Ca^{2+} . $K_{Ca4.1}$ is regulated by Na^+ , $K_{Ca4.2}$ is regulated by Cl^- , and K_{Ca5} is regulated by OH^- . The nomenclature of these channels will likely be changed to reflect their different mode of regulation in the future.

The structurally related cyclic nucleotide-gated (CNG) ion channels (six family members) and hyperpolarization-activated CNG (HCN) ion channels (four family members) are composed of four subunits that each have a 6-TM voltage-gated ion channel domain attached to an intracellular cyclic nucleotide-binding domain at their C-terminus. Like K_v channels, they form heterotetramers within each structural subfamily, and this contributes to their diversity of function. These channels were first purified and cloned from retinal rods, where they conduct the dark current that underlies visual signal transduction. Upon capture of photons by rhodopsin, activation of a G-protein-signaling pathway leads to the activation of a cyclic nucleotide phosphodiesterase that hydrolyzes cyclic guanosine monophosphate (cGMP). Reduction in the cGMP concentration in the rod outer segment closes these dark-current channels, causing hyperpolarization and initiation of visual signal transduction to the neural cells of the retina. Closely related CNG channels are responsible for olfactory signal transduction in the nasal epithelium. The more distantly related HCN channels are involved in cyclic nucleotide-regulated pacemaking in cells that generate repetitive action potentials, like the sino-atrial node pacemaker cells of the heart and the persistently firing neurons of the thalamus in the brain. They are also involved in sensation of sour tastes in taste buds. Remarkably, they are activated by hyperpolarization (rather than depolarization) via their S4 voltage sensor, and their opening by hyperpolarization is greatly enhanced by simultaneous binding of cyclic adenosine monophosphate (cAMP) and/or cGMP.

The transient receptor potential (TRP) channels were discovered first in *Drosophila*, where the founding member is the site of mutations that cause the TRP phenotype that alters visual signal transduction in the eye. Subsequent to that work, a family of 32 related channels, which can be divided into six subfamilies, have been defined in mammals. These channels are weakly voltage sensitive, are either calcium selective or nonselective cation channels that conduct calcium, and are activated by a range of signals including heat, cold, and intracellular lipid messengers. The TRPC subfamily of channels is most closely related to the classical *Drosophila* TRP channel. The TRPV subfamily of channels is related to the vanilloid receptor (TRPV1), a channel protein that serves as a receptor for the hot chili pepper ingredient capsaicin, a vanilloid compound. It also responds to heat and mediates noxious thermal pain sensations. The TRPM subfamily is most closely related to melastatin, first discovered as a tumor marker in melanoma. TRPM7, the first member of this family to be functionally

expressed, is slightly calcium selective and contains an intrinsic protein kinase domain that may autophosphorylate to activate its ion channel domain. The TRPP, CatSper, and TRPML subfamilies of ion channel subunits are also related to TRP channels. CatSper plays an essential role in calcium signaling in sperm. The TRPP channels are involved in sensing fluid transport in the kidney and other epithelial tissues. TRPML channels may be involved in auditory signaling in the ear and in calcium transport regulating lysosome function.

Inwardly Rectifying Potassium Channels and Their Relatives

The inwardly rectifying potassium channels (K_{ir}) are the structurally simplest ion channels, containing four subunits, each having two transmembrane segments and a membrane-reentrant pore loop between them (Figure 1). As their name implies, they conduct potassium more effectively inward than outward, but their outward conductance of potassium is physiologically important to polarize cells near the resting membrane potential. They are structurally related to the S5 and S6 segments of the voltage-gated ion channels, and their pore loop forms the extracellular end of the pore as in the K_v family of proteins. The two transmembrane segments and the pore loop of a related bacterial potassium channel have been shown directly by X-ray crystallography to form an ion-selective pore (Figure 2(a)). Many inwardly rectifying potassium channels are gated by intracellular divalent cations that bind in their pore, including Mg, spermine, and spermidine. The X-ray structure of a related vertebrate inwardly rectifying potassium channel reveals an extended pore region that projects into the cytoplasm and contains divalent cation-binding sites that may control ion flow through the pore. Other K_{ir} channels are gated by direct binding of G protein $\beta\gamma$ -subunits and inositol phospholipid messengers. Remarkably, adenosine triphosphate (ATP)-sensitive potassium channels are composed of an inwardly rectifying potassium channel core in association with the much larger sulfonylurea receptor (SUR) protein, a member of the ABC transporter family that binds adenosine diphosphate and ATP and regulates the function of the inwardly rectifying potassium channel. These channels are crucial regulators of insulin secretion from pancreatic beta cells controlled by intracellular glucose and ATP levels, and SUR is the molecular target for the sulfonylurea drugs used in treatment of diabetes.

Two-Pore-Motif Potassium Channels

The most recently discovered family of ion channels are potassium channels that have two repeats of the inward rectifier pore motif and are designated K_{2P} (Figure 1). The channels function as open rectifiers; that is, they are constitutively open and constantly drive the membrane potential toward the potassium equilibrium potential by mediating outward potassium conductance. They are thought to be important for setting the resting membrane potential of excitable cells at a negative value near the equilibrium potential for potassium of -80 mV. Although their physiological regulatory mechanisms

Figure 2 Structures of K⁺ channels. (a) Open and closed conformations of K⁺ channel pore structures. Two subunits of the bacterial potassium channel KcsA representing a closed conformation and MthK representing an open conformation are shown in the figure. The selectivity filter is orange and the outer helix (M1) is depicted adjacent to the lipid bilayer. The inner helix (M2) is marked with space-filling model of the conserved glycine residue (red), which is thought to be critical for the bending of M2 helix in the open conformation. (b) Cross section through the three-dimensional structure of a tetrameric K_v1.2 channel. Center, the pore regions S5-P-S6 of two subunits, designated 1 and 3, in blue-green. Left, S1 through S4 of subunit 4, whose S5-P-S6 segments project in front of the plane of the figure and form the near side of the pore. Right, S1 through S4 segments of subunit 2, whose S5-P-S6 segments project behind the plane of the figure and form the far side of the pore. As illustrated, the voltage-sensing domain composed of the S1–S4 segments is positioned to interact with the S5-P-S6 segments of the adjacent subunit located clockwise (as seen from the extracellular side) in the symmetrical tetrameric array.

are not yet fully defined, they may be an important target for the actions of inhalation anesthetics, which activate these channels and thereby could prevent action potential firing in the brain during general anesthesia.

Structure and Function

Viewed from the perspective of the entire ion channel protein family, the functions of these proteins can be divided into three complementary aspects: ion conductance, pore gating, and regulation. All members of the family share a common pore motif, with variations appropriate to determine their different ion selectivity. It is likely that this pore motif first evolved in the bacterial ion channels that resemble inward rectifiers. The X-ray crystal structure of one of these channels has shown that the narrow outer mouth of the pore is formed by the pore loops between the M1 and M2 segments that are analogous to the S5 and S6 transmembrane segments of the 6-TM family members while the length of the pore is formed by a tilted bundle, inverted teepee arrangement of the M2 segments (Figure 2(a)). This structure suggests that the pore is closed

at its intracellular end and discriminates ions at the narrow ion selectivity filter at its extracellular end. This model of pore formation fits well with a wealth of structure–function data on the voltage-gated ion channels and the CNG channels. The closure of the pore at the intracellular end suggests that this is the site of pore gating. Support for this idea comes from classical biophysical studies and from more recent work. The structure of a calcium-activated bacterial potassium channel with calcium bound shows that the crossing of the M2 segments at the intracellular end of the pore is opened by bending of the helix, consistent with the hypothesis that this is the mechanism of pore opening (Figure 2(a)).

The different protein families within the ion channel superfamily are regulated by different mechanisms. The simplest family members, the inwardly rectifying potassium channels, are gated extrinsically by divalent cations binding in the pore or by binding of other regulators. The CNG ion channels and the calcium-activated potassium channels are gated by ligand binding to their carboxy-terminal regulatory domains. These ligand-induced conformational changes are thought to exert a torque on the connected S6 segments and force the opening of the pore bundle of S6 helices. In addition, the HCN channels and the K_{Ca}1 channels are also gated synergistically by changes in membrane potential and are highly sensitive to small voltage changes.

The voltage-gated sodium, calcium, and potassium channels are primarily gated by changes in membrane potential. Their regulation depends on the S1–S4 segments of these channels, which can be viewed as an evolutionary addition to the pore-forming segments. The structure of this bundle of four alpha helices is illustrated in Figure 2(b). The detailed mechanism of voltage-dependent gating is the subject of intense research. However, there is clear structure–function evidence for an outward and rotational movement of the positively charged S4 segments during the gating process, and it is assumed that the conformational change in the voltage-sensing module accompanying this outward movement exerts a torque on the bundle of four S6 segments at the intracellular end of the pore forcing the bundle to open. This conformational change is thought to be mediated by bending of the S6 helix at conserved glycine or proline hinge regions.

Voltage-dependent gating of the sodium and calcium channels is also modulated by binding of calcium/calmodulin and other effectors to the C-terminal domain, suggesting that these interactions may also exert a torque on the S6 segments and thereby alter the energetics of gating.

Conclusion

The voltage-gated ion channel superfamily is one of the largest families of signaling proteins, following the G-protein-coupled receptors and the protein kinases in the number of family members. The family is likely to have evolved from 2-TM ancestors such as the modern inwardly rectifying potassium channels and bacterial potassium channels. Modular additions of intracellular regulatory domains for ligand binding and a 4-TM transmembrane domain for voltage gating have produced extraordinarily versatile signaling molecules with capacity to respond to voltage signals and intracellular effectors and to

integrate information coming from these two types of inputs. The resulting signaling mechanisms control most aspects of cell physiology and underlie complex integrative processes such as learning and memory in the brain and coordinated movements of muscles. The evolutionary appearance and refinement of these signaling mechanisms is one of the hallmark events allowing the development of complex multicellular organisms.

Glossary

Agonist A substance that binds to a receptor and causes its activation.

Ataxia A neurological symptom that shows dysfunction of the coordinate movement.

Ca²⁺ oscillation Fluctuation of intracellular Ca²⁺ concentration.

Endoplasmic reticulum An intracellular organelle that stores Ca²⁺.

Phosphoinositides A glycerol backbone attached to two fatty acids (stearoyl at position 1 and arachidonyl at position 2) and inositol (linked at position 3 by a

phosphodiester bond). The inositol headgroup can also be further phosphorylated.

Phospholipase C A class of enzymes that catalyze cleavage of the diacylglycerolphosphate bond of a glycerophospholipid. In the process, phosphatidylinositol 4,5 bisphosphate (PIP₂) is cleaved into diacylglycerol (DAG) and IP₃.

Synaptic plasticity Change of synaptic transmission efficacy between neurons. At long-term potentiation, the efficacy is increased for long time; at long-term depression, the efficacy is decreased for long time. Both are important neurochemical basis of learning and memory.

A Brief History

The importance of intracellular Ca²⁺ concentration had been noticed since 1883 when Sidney Ringer discovered the requirement of Ca²⁺ in the contraction of frog hearts. From that time, the crucial roles of cytosolic Ca²⁺ elevation in various physiological events such as contraction, secretion, and development had been noticed, and the mechanisms by which extracellular multiple stimuli induce the cytosolic Ca²⁺ dynamics had been investigated. In the early 1950s, Hokin and Hokin found that acetylcholine increases the turnover of phosphoinositides in the pancreatic acinar cells, and, several years later, Bob Michell proposed a physiological link between extracellular stimuli-induced phosphoinositide hydrolysis and intracellular Ca²⁺ elevation. After a long debate on whether Ca²⁺ signals were causes or results of phosphoinositide hydrolysis, the production of IP₃ from PIP₂ by phospholipase C was confirmed, and Micheal Berridge, Robin Irvine, Iren Schulz, and their colleague demonstrated that IP₃ induces Ca²⁺ release from the internal Ca²⁺ stores in 1983. An attempt to purify the IP₃ binding protein to characterize the molecule was initiated by many research groups including universities and pharmaceutical companies. The IP₃ receptor protein was also characterized as a phospho- and glycoprotein abundant in the cerebellum, and named PCPP-260, GP-A, or P₄₀₀ which was absent in the cerebellum of ataxic mutant mice. General molecular properties of IP₃ receptor were made clear when the whole sequence of P₄₀₀ was determined and P₄₀₀ was found to be the IP₃ receptor by Katsuhiko Mikoshiba in 1989.

Since then, countless researchers have analyzed the nature of IP₃ receptors such as the subtypes in diverse organisms, the affinity for IP₃, the expression patterns in tissues, conformation, and regulatory mechanisms by Ca²⁺, adenosine triphosphate, and numerous proteins. Now, it is well established that IP₃ receptor is a cation-selective channel localized at endoplasmic reticulum and generates complex patterns of intracellular Ca²⁺ signals, which is crucial for many physiological events (Figure 1).

Structure of IP₃ Receptors

IP₃ receptor has been found in organisms from nematode to human. Three subtypes of IP₃ receptors encoded by distinct genes (~2700 amino acid residues) are reported in vertebrates, whereas only a single gene is reported in organisms such as *Drosophila melanogaster* and *Caenorhabditis elegans*. The three subtypes of IP₃ receptors have distinct features in the affinity for IP₃, tissue distribution, the Ca²⁺ sensitivity, and the modulation by various associated proteins. IP₃ receptor is constituted of four subunits forming a Ca²⁺-permeable pore at the center. Each subunit of IP₃ receptor has three domains, the N-terminal cytoplasmic domain, a transmembrane domain near the C-terminus, and the short C-terminal cytoplasmic domain (also named as a gate keeper domain) (Figure 2). The large N-terminal cytoplasmic domain is further divided into three domains, the N-terminal coupling domain, the IP₃ binding domain, and the internal coupling domain.

Recently, crystal structures of the N-terminal coupling domain and the IP₃ binding domain were resolved (Figure 3). The N-terminal coupling domain (residues 1–225) has a globular head domain containing the β -trefoil fold and an arm domain constituted of a helix–turn–helix (Figure 3(a)). Interestingly, the deletion of the N-terminal coupling domain resulted in no functional Ca²⁺ channels. Further, the N-terminal coupling domain determines the specific affinity for IP₃ by suppressing the IP₃-binding core region: without this region, the three subtypes of IP₃ receptors show enhanced IP₃ affinity and presented the similar affinities for IP₃ among three isoforms. Therefore, the region is originally named as ‘N-terminal suppressor domain’. On the other hand, the IP₃ binding domain (residues 224–604) forms the L-shaped structure composed of the three domains: the N-terminal β -trefoil domain, the C-terminal α -helical domain, and a hinge region linking the N- and the C-terminal domains (Figure 3(b)). The cleft between the N- and the C-terminal domains contains a cluster of basic residues on the surface, which contributes to the coordination with the three phosphoryl groups of IP₃.

Figure 1 The signal transduction cascades for Ca^{2+} mobilization via IP_3 receptor. Extracellular stimuli stimulate phospholipase C ($\text{PLC}\beta$ or $\text{PLC}\gamma$) activities through two different types of receptors. Seven membrane-spanning G-protein-coupled receptors activate $\text{PLC}\beta$ through the dissociated α -subunit of G proteins bound to the receptors. $\text{PLC}\gamma$ is activated when it associates with and phosphorylated by receptors with either intrinsic or associated protein tyrosine kinase activity. Phospholipase C hydrolyzes PIP_2 in the plasma membrane and produces IP_3 and diacylglycerol. Then, the produced IP_3 binds to and activates the IP_3 receptor on the endoplasmic reticulum (ER) and generates the complex patterns of intracellular Ca^{2+} concentration.

Figure 2 (a) Structure of the mouse IP_3 receptor type 1. (b) Topology of the IP_3 receptor. IP_3 receptor is a large protein and is constituted from the four homo- or hetero-tetramers. Two monomers of the four subunits are illustrated. Each subunit has six transmembranes (TM1–6) and the loop domain between M5 and M6 contributes to a pore formation of IP_3 receptor. IP_3 binds to the IP_3 binding domains near the NH_2 -terminus, which somehow triggers the gating of the channel pore localized near the COOH -terminus. Modified from figure 24-1 in Lajtha A (ed.) (2009) *Handbook of Neurochemistry and Molecular Neurobiology. Neural Signaling Mechanisms*, 3rd edn., ch. 24, pp. 442–455 and ch. 31, pp. 566–575. New York: Springer.

(2005) Crystal structure of the ligand binding suppressor domain of type I inositol 1,4,5-triphosphate receptor. *Molecular Cell* 17: 193–203. (b) Reproduced from figure 2(a) in Bosanac I, Alattia JR, Mal TK, et al. (2002) Structure of the inositol 1,4,5-triphosphate receptor binding core in complex with its ligand. *Nature* 420: 696–700, with permission. (c, d) Reproduced from figures 2(a) and 4d from Sato C, Hamada K, Ogura T, et al. (2004) Inositol 1,4,5-triphosphate receptor contains multiple cavities and L-shaped ligand-binding domains. *Journal of Molecular Biology* 336: 155–164, with permission.

The transmembrane domain has six membrane-spanning helices (TM1–TM6) and is responsible for the tetramer formation of four subunits of IP₃ receptor (Figure 1(b)). The TM5–TM6 region of each subunit of IP₃ receptor contributes to a pore formation. High homologies of the pore region of IP₃ receptor with other cation channels suggest the conservation of structural organization.

Three-dimensional structure of IP₃ receptor in the IP₃-unbound state has also been resolved at high resolution (15 Å) using cryo electron microscopic images of the receptor. The tetrameric IP₃ receptors have a hot-air balloon-like shape (total height of 231 Å) with the spherical cytoplasmic domain (diameter of 175 Å) and the square-shaped luminal domain (side length of 96 Å) (Figure 3(c)). The transmembrane domain is 30 Å in thickness. Prominent L-shaped densities were found in the spherical cytoplasmic region of the three-dimensional structure, and estimated as the L-shaped IP₃ binding domains determined by X-ray described above (Figure 3(d)).

Regulation of IP₃ Receptors by IP₃ and Ca²⁺

The accumulating evidence suggests that IP₃ receptor requires not only IP₃ but also Ca²⁺ to open. Therefore, both IP₃ and Ca²⁺ are regarded as co-agonists of the receptor. However, the

effect of Ca²⁺ on the channel activities is more complex than IP₃: Ca²⁺ affects IP₃ receptor as an agonist at the lower concentration, while it inhibits the channel activity at the higher concentration. Thus, the effect of Ca²⁺ on the IP₃ receptor is biphasic, and this property is called as a bell-shaped Ca²⁺ dependence of IP₃ receptor. Further, IP₃ concentration also modulates the effect of Ca²⁺: at the lower IP₃ concentration, IP₃ receptors are sensitive to Ca²⁺ and tends to close before full activation, while a higher concentration of IP₃ relieves the inhibition by Ca²⁺. These fundamental complex regulations of IP₃ receptor by Ca²⁺ and IP₃ are thought to generate the various intracellular Ca²⁺ patterns, such as Ca²⁺ wave and Ca²⁺ oscillation. How Ca²⁺ affects the channel activities of the receptor is not clear, but the eight putative Ca²⁺ binding sites and several calmodulin/Ca²⁺-binding sites are proposed in the IP₃ receptor.

Physiological Roles of IP₃ Receptors

The three types of mammalian IP₃ receptors (IP₃R1, IP₃R2, and IP₃R3) show 60–70% homologies, but their distributions in tissues are quite different. While IP₃R1 is predominantly expressed in the central nervous system, especially in Purkinje cells in the cerebellum, IP₃R2 and IP₃R3 are rather broadly

expressed in almost all tissues with different ratios. Using the pharmacological tools, the functional inhibitory antibody, and a gene knockout technology, the physiological roles of IP₃Rs in various phenomena have been revealed including development, contraction, proliferation, and apoptosis. During development, IP₃R is involved in fertilization. In many species, when the sperm is attached to the unfertilized eggs, a large Ca²⁺ transient occurs at the contact site and it propagates to the opposite side across, like a wave. IP₃R is essential for achieving the Ca²⁺ waves, and, if inhibited, some early and late events of egg's activation are disturbed. IP₃R is also involved in determination of dorso-ventral axis formation in *Xenopus*: injection of functionally inhibitory antibodies for IP₃R into ventral side of early embryos induces an ectopic dorsal axis. Deletion of IP₃R in *Drosophila* leads to the lowered levels of a hormone ecdysone, and the mutant results in lethal because of the delayed molting.

In the mammalian brain, IP₃R1 plays crucial roles in synaptic plasticity and neuronal development. The mice deficient in IP₃R1 represent tremor and cerebellar ataxia, and show the deficit of the cerebellar long-term depression, a form of synaptic plasticity. On the other hand, long-term potentiation in hippocampus is enhanced. The importance of IP₃R1 in the human brain function is also demonstrated by recent studies, which point out mutation or deletion of the IP₃R1 gene underlies the cause for patients of spinocerebellar ataxia type 15 and 16. Further, the disturbed regulation of IP₃R activity by associated proteins including Huntingtin is proposed to be involved in the onset of disease in mice model.

IP₃R2 and IP₃R3 in mice play important roles in exocrine secretion, such as saliva, pancreatic juice, and olfactory mucus. The phenotype is like human Sjogren syndrome, where IP₃ receptor antibodies are detected in the serum of nearly 50% of the patients. IP₃R3 contributes to the signal transduction of taste perception in taste buds.

Glossary

Fe–S active sites Sites in proteins containing iron ligated to inorganic sulfide and/or cysteine sulfur.

Iron–sulfur clusters The form in which irons and sulfides are organized in Fe–S proteins.

Iron–sulfur proteins Proteins that contain iron and sulfur, active mostly (even if not exclusively) in electron transfer.

Iron–Sulfur Clusters

Nomenclature and Shorthand Designations

The conventions for the nomenclature of iron–sulfur (Fe–S) clusters and Fe–S proteins are found in the 1989 recommendations of the Nomenclature Committee of the International Union of Biochemistry (IUB), now International Union of Biochemistry and Molecular Biology (IUBMB). The components of the cluster core are placed into brackets, and the oxidation level of the core (not including that of ligands) is given as a superscript $[2\text{Fe–}2\text{S}]^{2+}$. The possible oxidation states of the species that can be formed are indicated as shown: $[2\text{Fe–}2\text{S}]^{2+,+}$. If the kind of ligands to this cluster is to be specified, the alternative designation $[\text{Fe}_2\text{S}_2(\text{RS})_2(\text{L}_2)]^{2-}$ should be used.

Structures

The simplest Fe–S protein and also the simplest building block of Fe–S proteins is the mononuclear thiolate complex $[\text{Fe}(\text{Cys})_4]^{2-/-}$ as it occurs in rubredoxins (Rds). However, in the great majority of Fe–S proteins the iron is present in clusters, with the irons linked by sulfides. The cluster types are shown in [Figure 1](#). The coordination is tetrahedral throughout. As evident from the figure, the S–S distances are ~ 1.3 times longer than the Fe–Fe distance, which produces the distorted cubic structure typical for $[4\text{Fe–}4\text{S}]$ clusters. The $[2\text{Fe–}2\text{S}]$ and $[4\text{Fe–}4\text{S}]$ clusters are the predominant species, and the $[3\text{Fe–}4\text{S}]$ cluster can be considered as a 4Fe cluster with one Fe missing. The cluster structures shown are, to some extent, interconvertible and the 3Fe cluster is central to all cluster interconversions. By partial denaturation of the protein, it can also be converted to a linear form: $(\text{Cys})_2\text{FeS}_2\text{FeS}_2(\text{Cys})_2$. The 3Fe cluster can serve as starting material for producing hetero-metal clusters with metals such as Zn, Ni, Co, Cd, Ga, Tl, and Mo; however, such clusters are not found in nature. Those that occur have modified structures and are formed by specific synthetic systems. The 4Fe to 3Fe cluster conversion is also used in nature to condition clusters for use as active sites in enzymes and for sensing functions.

Stability

Sulfur is a weak-field ligand, allowing the iron to remain in the high-spin state, which makes the ligands relatively labile as

compared to strong ligands such as cyanide. Fe–S clusters are rather malleable, and from high-resolution X-ray structures it is apparent that they can be distorted by influences from the protein and can be adapted for various conditions and functions. The isolated clusters undergo facile ligand exchange with thiol compounds, a process that is relevant to the interconversions that occur during the assembly of Fe–S proteins. Fe–S clusters are sensitive to oxidants such as oxygen and its reduction products, and to NO, and also to an excess of their own constituents, namely S^{2-} and RS^- , to dithiothreitol and dithionite, and toward hydrolysis at high or low pH. As mentioned above, Cys ligands belonging to protein frameworks are required for the formation of stable clusters. Replacement of one Cys with another functional residue is allowed in some clusters; however, the only clusters that are known to be stable with two non-Cys ligands are those with two histidine (His) ligands, as they occur naturally in the so-called ‘Rieske’ proteins. While polypeptide chains are mandatory for the stabilization of Fe–S clusters, their protecting effect is very variable; the lifetime of Fe–S proteins in air may vary from seconds to weeks. As naturally occurring Fe–S clusters require protein ligands for support, their functions are considered later in this article (see section [Iron–Sulfur Proteins](#)).

Electronic Structure and Magnetism

The electronic charge in Fe–S clusters is concentrated at their sulfides and Cys ligands. It has been shown by X-ray near-edge spectroscopy (XANES) that all bonds involving sulfur are highly covalent, with those involving sulfide exhibiting 2–3 times the covalency of the thiolate bonds. By contrast, the unpaired spin density resides primarily on the irons. Fe–S clusters owe many of their characteristic properties to the ordering of their spin systems. This ordering is dominated by three forces: (1) the tendency to pair the spins antiparallel, which is expressed in the magnitude of the spin coupling parameter J ; (2) the tendency to pair the spins parallel, expressed in the parameter B , the resonance integral (this tendency arises when an extra electron is present, leading to spin-dependent electron delocalization (SDD)); and (3) the dynamic trapping energy, arising through vibronic coupling with groups in the neighborhood. On one-electron reduction of $[2\text{Fe–}2\text{S}]^{2+}$ (2Fe^{III}) clusters, the trapping energy leads almost invariably

[†]Deceased.

to antiparallel coupling and localization of the electron at one Fe (1Fe^{III} , 1Fe^{II}) so that the system spin $S = 5/2 - 4/2 = 1/2$. In $[4\text{Fe}-4\text{S}]^{2+}$ clusters, there are two pairs of parallel-coupled (according to SDD) mixed valence irons (2Fe^{II} , 2Fe^{III}), both with $S = 5/2 + 4/2 = 9/2$, which then couple antiparallel to $S = 0$. On addition of an electron, there will be one mixed valence pair and two Fe^{II} ; thus, $S = 9/2 - 2 \times 4/2 = 1/2$, that is, paramagnetism. If instead one electron is removed from the $2+$ level to form $[4\text{Fe}-4\text{S}]^{3+}$ (3Fe^{III} , 1Fe^{II}), there are one mixed valence pair and two Fe^{III} ; thus, $S = 2 \times 5/2 - 9/2 = 1/2$ and paramagnetism. The $[4\text{Fe}-4\text{S}]^{3+}$ level has been first observed in so-called high-potential iron protein (HiPIP); these proteins are now counted among ferredoxins (Fds) with high redox potentials. Occasionally, $[4\text{Fe}-4\text{S}]^+$ clusters with an $S = 3/2$, a mixed $1/2$ and $3/2$, or higher ground-state spins have been observed.

Iron-Sulfur Proteins

Nomenclature

Small proteins, whose function is electron transfer, are called rubredoxins (Rds) if they contain only mononuclear $[\text{Fe}(\text{Cys})_4]$ complexes and Fds if they contain only $[2\text{Fe}-2\text{S}]$ or $[4\text{Fe}-4\text{S}]$ clusters. Many Fe-S clusters also occur in large and sometimes membrane-bound proteins, together with other prosthetic groups and/or metal cofactors. These proteins are designated complex Fe-S proteins.

Primary Structure

In the amino-acid sequences of many Fe-S proteins, the active sites can be recognized from characteristic patterns of Cys ligands. For instance, the Fe ion in Rd is ligated by two $-\text{C}-\text{x}_2-\text{C}-$ motifs (x standing for residues other than Cys) separated by 20–30 residues. In plant- and mammalian-type $[2\text{Fe}-2\text{S}]$ Fds, the pattern is $-\text{C}-\text{x}_{4,5}-\text{C}-\text{x}_2-\text{C}-\text{x}_n-\text{C}-$, with $n \approx 30$. In Rieske-type $[2\text{Fe}-2\text{S}]$ proteins, the two Cys ligands of one iron and the two His ligands of the other one occur in a $-\text{C}-\text{x}-\text{H}-\text{x}_{15-17}-\text{C}-\text{x}_2-\text{H}-$ pattern. These proteins are found in membrane-bound enzymes in conjunction with *b*-type cytochromes in mitochondria ($b_{\text{c}1}$, or complex III) and chloroplasts (b_6/f), as well as in soluble bacterial dioxygenases. In $[4\text{Fe}-4\text{S}]$ Fds, the canonical pattern is $-\text{C}-\text{x}_2-\text{C}-\text{x}_2-\text{C}-\text{x}_n-\text{C}-$, with $n \approx 20-40$. This pattern is duplicated in Fds containing two $[4\text{Fe}-4\text{S}]$ clusters. Omission of one Cys from this sequence

(usually the third) gives rise to a $[3\text{Fe}-4\text{S}]$ cluster. Similar patterns containing the ligands in Rd and Fd are observed in the larger sequences of many redox enzymes. Significant diversification has occurred, through insertions or deletions of intervening loops of residues. In addition to these canonical sequences, an increasing number of novel Cys patterns are found to furnish ligands to $[2\text{Fe}-2\text{S}]$ and $[4\text{Fe}-4\text{S}]$ sites.

Even though non-Cys ligation of Fe-S active sites is less common, it is functionally important as a means of modulating chemical reactivity or redox potential. Several crystal structures of Fe-S active sites with His, Ser, or carboxylate ligands have now been determined. In some of these, non-Cys ligands are naturally present; in others they have been introduced by site-directed mutagenesis.

Secondary and Tertiary Structure

Many three-dimensional structures of Fe-S proteins have now been determined by X-ray crystallography. At an early stage, the structures of the small Rds and Fds revealed characteristic folds, each specific for a given Fe-S structural framework. The Rd molecule is composed of a three-stranded pleated sheet and two loops that bear a $-\text{C}-\text{x}_2-\text{C}-$ ligand pair each. These two loops are related by a pseudo-twofold symmetry axis passing through the iron atom. Some zinc-finger modules in which the zinc ion has four Cys ligands are structurally very similar to Rd. Plant- and mammalian-type $[2\text{Fe}-2\text{S}]$ Fds assume a structure named β -grasp, of which the main framework is a five-stranded antiparallel β -sheet with an α -helix lying on top of it. The remainder of the structure consists of short secondary elements and loops. Prominent among the latter is a surface loop, including three of the four Cys ligands of the cluster. Another type of $[2\text{Fe}-2\text{S}]$ Fd has a structure closely related to that of thioredoxin. The protein fold of Rieske proteins around their $[2\text{Fe}-2\text{S}]$ active site is superimposable on the Rd fold; the His-ligated iron is the one closest to the protein surface. In $2[4\text{Fe}-4\text{S}]$ Fds, the two $[4\text{Fe}-4\text{S}]$ clusters are surrounded by two pairs of antiparallel β -strands on one side and two α -helices on the other. The structure displays a conspicuous twofold symmetry as a consequence of the sequence duplication. In high-potential Fd (HiPIP), a sizeable part (40%) of the structure is composed of hairpin turns while the remainder consists of several short strands and helices. Consequently, the $[4\text{Fe}-4\text{S}]$ cluster is deeply buried in a hydrophobic cavity that stabilizes its oxidized $3+$ state. The structural frameworks

of the [2Fe–2S] Fd and low-potential [4Fe–4S] Fd are ubiquitous and occur not only in small soluble Fds but also in subunits and domains of many redox enzymes. The low-potential [4Fe–4S] Fd-fold is particularly versatile, and insertions and deletions inferred from sequence alignments have been substantiated by crystal structures. In addition to variations in sequence length, cases of cluster modification or loss have been observed.

Higher-Order Structures

While the canonical Fe–S protein folds described above have long dominated the landscape, numerous novel folds are revealed by the rapid growth of structural databases. It was predictable that polypeptide chains can fold in many different ways to position Cys residues appropriately for the binding of [2Fe–2S] or [4Fe–4S] active sites. Indeed, for the accommodation of [4Fe–4S] clusters alone, well over 30 distinct protein folds have now been structurally characterized. In AdoMet radical proteins, a specific pattern including the sequence C–x3–C–x2–C– binds a [4Fe–4S] cluster with three Cys residues and one open iron site. There are cases of [4Fe–4S] clusters held in proteins between two subunits, each of which provides two of the four Cys ligands, as in nitrogenase Fe-protein and photosystem I centre F_X .

Complex Fe–S Proteins with Clusters of High Nuclearity and Hetero-Metal Clusters

A yet higher level of complexity is displayed by proteins containing large metaloclusters, which, in several cases, belong to the Fe–S family (Figure 2). Some of these superclusters can be considered as derived from [4Fe–4S] clusters without (e.g., P clusters of nitrogenase) or with a metal atom other than Fe (Mo or V in nitrogenase, and Ni in carbon monoxide

dehydrogenase). In nitrite and sulfite reductases, a [4Fe–4S] cluster is covalently bound through a cysteine ligand to the central iron of siroheme. Protein ligands other than Cys (His, Ser, peptidyl-N) or nonprotein ligands (homocitrate, dithiols, CO, and CN^-) are also involved. The protein frameworks that accommodate these large clusters are generally bigger and more sophisticated than those of the usual Fe–S clusters. Nevertheless, it is noted that a number of them are assemblages of smaller substructures such as Rossmann folds.

Structural Flexibility in Relation to Function

Atomic resolution (1.2 Å or better) X-ray crystallography has become more accessible through technical improvements (synchrotron radiation and low temperature) and allows the detection of minute structural deviations that are imposed by the polypeptide chain or occur upon redox transitions. Crystal structures may convey the misleading impression that proteins are rigid structures; however, Fe–S proteins have malleable metal sites associated with flexible polypeptide chains. While essential functions of Fe–S proteins, electron transfer in particular, are indeed optimized through minimization of structural flexibility, many other functions, such as cluster assembly or response to oxidative stress, require structural reorganizations of the polypeptide chain. Such modifications have long been known to occur upon degradation (oxidative denaturation and loss of iron) of some Fe–S proteins. A notable exception is the 3Fe/4Fe interconversion, which may occur with minimal protein reorganization. Other modifications of cluster nuclearity are expected to be associated with significant protein movements, since the Cys ligand sets of the [1Fe], [2Fe–2S], and [4Fe–4S] sites have very different spatial distributions. Flexibility of both the metal site and the polypeptide chain is a necessity in proteins committed to sensing and transducing signals which may depend on redox state or metal concentration. Such

Figure 2 Superclusters: (a) the P cluster in the Fe–Mo protein of nitrogenase; (b) MoFe-cofactor, with bound homocitrate; and (c) H-cluster of the FeFe-hydrogenase.

structural changes may be classified in two main groups, according to whether it is the polypeptide chain (protein-driven reorganization of the metal site) or the metal site (cluster-driven protein movements) that assumes the leading role. Examples of the latter, where polypeptide chain movements are driven by the avidity of Fe–S clusters for Cys ligands, have been structurally characterized.

Functions

Stabilization of Protein Structures

In some enzymes, the network of ligands around a Fe–S cluster is used to stabilize specific structures. The covalent structures, particularly of [4Fe–4S] clusters, can improve protein rigidity. This provides an explanation for the existence of some highly conserved clusters in proteins, such as some DNA-repair helicases. However, in most cases, another distinct function can be found for the existence of the clusters.

Electron Transfer

Many complex Fe–S proteins contain clusters, arranged in chains, separated 1–1.4 nm apart, which allow facile electron transfer across considerable distances. Other electron-transferring groups such as heme or flavin may also be present. Examples include the electron transport chains of mitochondrial respiration (complexes I, II, and III) and photosynthesis (photosystem I), and enzymes such as hydrogenase, nitrogenase, and xanthine dehydrogenase.

Oxidation and reduction of clusters occur with minimal reorganization energy, which means that very rapid electron transfer (in less than microseconds) is possible, for example, in the primary electron-transfer processes of photosynthesis. The oxidation–reduction potentials of the Fe–S clusters determine the overall direction of electron transfer. However, in some electron-transfer chains, an uphill step from a more positive to a more negative potential center does not appear to act as a barrier as long as the overall electron transfer is favorable. Redox potentials reported in other compendia have been collected, and representative ranges for various types of Fe–S clusters are summarized in [Figure 1](#). Multiple factors influence the redox potential range of Fe–S proteins. First, the electronic structure of the Fe–S framework. Second, as each iron ion can be in either the Fe(III) or the Fe(II) state, clusters of n Fe atoms are in principle endowed with $n - 1$ redox transitions. This is observed in nature only in the case of the [4Fe–4S] clusters (3+/2+, 2+/+, and 1+/0 transitions). Third, the redox potentials of Fe–S clusters can be modified by several parameters that are adjustable by the polypeptide chain. These include cluster ligation (sulfur, nitrogen, or oxygen), polarity of the medium, and neighboring charges. Studies of synthetic analogs and proteins, native as well as mutated, have shown that variations of each of these parameters can cause redox potential shifts of 50 mV or more. For instance, in Rieske-type proteins, the presence of two His ligands on the same Fe raises the redox potential of this Fe sufficiently so that it becomes reducible at a much higher potential than that of all Cys-ligated [2Fe–2S] active sites ([Figure 1](#)). Moreover, for some of these proteins, reduction is accompanied by protonation, which compensates

for the electron charge; as a result, the redox potential of Rieske clusters is pH dependent.

Generation of unusual reducing power

In a number of enzymes, a reduced 4Fe cluster, in conjunction with the hydrolysis of MgATP, is used to achieve reductions requiring potential differences of more than 1 V, for the reduction of dinitrogen by nitrogenase, and of a porphyrin ring by the light-independent protochlorophyllide reductase. In these enzymes, the [4Fe–4S] cluster is located between two subunits of a protein, each contributing two Cys ligands, and each binding one molecule of adenosine triphosphate (ATP) which is hydrolyzed during electron transfer. The resultant conformational change in the cluster can generate very low redox potentials, with [4Fe–4S] clusters even being reduced by two electrons to the all-ferrous [4Fe–4S]⁰ state.

Catalytic Fe–S Clusters

As already noted, the most common function of Fe–S proteins is electron transfer, and the clusters are fully coordinated by ligands such as Cys. However, some enzymes, probably originating from more primitive forms of life, use Fe–S clusters directly in catalysis, and these often have a free iron position for binding to substrates or other ligands. Some examples of these are shown in [Figure 3](#).

In aconitase, a nonredox enzyme, the unique iron is able to extend its coordination from four to six coordinate and bind the substrates, citrate, or isocitrate ([Figure 3\(a\)](#)). It can thus serve as a Lewis acid in the dehydration of the substrate to *cis*-aconitate and the rehydration to the alternate substrate with inversion of the positions of the H and OH substituents.

Initiation of radical reactions

There are a number of enzymes that use free-radical chemistry supported by adenosylmethionine to achieve substitutions on unactivated carbon atoms. These so-called ‘radical SAM’ enzymes contain a [4Fe–4S]⁺ cluster with only three Cys ligands, which binds S-adenosylmethionine (AdoMet) ([Figure 3\(b\)](#)). Electron transfer from the cluster splits adenosylmethionine and generates a 5′deoxyadenosyl radical, which is analogous to those produced by cobalamin (vitamin B₁₂)-dependent enzymes. The radical is then used to catalyze difficult synthetic reactions in a wide variety of metabolic processes. In some cases, the AdoMet radical acts catalytically in the enzyme, for example, in lysine 2,3-aminomutase. In others, the radical is employed to generate another protein-bound radical, which is required for catalysis; for example, AdoMet-dependent activating enzymes generate essential glycol radicals in pyruvate formate-lyase and the ribonucleoside triphosphate reductase III of anaerobic bacteria. Other enzymes consume AdoMet in the transfer of sulfur from cysteine into biotin and lipoic acid, and the thiomethylation of transfer RNA.

Reduction of disulfide bonds

During redox reactions, Fe–S clusters usually transfer one electron at a time, but reduction of disulfide bonds requires two reducing equivalents. Plant ferredoxin:thioredoxin reductase achieves the reduction of the disulfide in thioredoxin by means of a unique [4Fe–4S] cluster extended by two cysteinate

Figure 3 [4Fe-4S] clusters in the catalytic centres of enzymes: (a) aconitase (citrate bound); (b) a representative AdoMet radical enzyme (AdoMet bound); and (c) ferredoxin:thioredoxin reductase.

ligands. These form a disulfide which extends the coordination sphere of one of the iron ions (Figure 3(c)). The cluster transiently assumes the $[4\text{Fe}-4\text{S}]^{3+}$ level and generates a sulfur radical, as indicated by electron paramagnetic resonance (EPR).

Sensing and regulatory functions

Fe-S clusters are labile toward oxygen and reactive oxygen species, and toward nitric oxide. Fe-S clusters can, therefore, also be used in nature as signaling or regulatory agents. While the Fe-S clusters of proteins that belong to this group may undergo one electron oxidation or complete oxidative destruction, the ensuing regulatory function involves specific interactions with DNA (SoxR and FNR) or RNA (iron regulatory protein (IRP)), which require either the presence (SoxR, FNR) or the complete absence (IRP) of the Fe-S cluster. Examples of this are the $[2\text{Fe}-2\text{S}]$ SoxR and $[4\text{Fe}-4\text{S}]$ FNR protein in bacteria and the IRP in eukaryotes. SoxR is a sensor for the superoxide anion that binds to DNA upstream of the *soxS* gene. Its oxidation-reduction potential is such that it normally occurs in the reduced $1+$ form in bacteria. Upon oxidation to the $2+$ level by the superoxide anion, a structural modification of the soxR-soxS nucleoprotein complex triggers expression of *soxS* and induction of the synthesis of defensive enzymes such as superoxide dismutase and other proteins. The FNR protein acts as oxygen sensor. Its 4Fe cluster is rapidly destroyed in the presence of oxygen, hence its ability to induce the synthesis of enzymes required for anaerobic respiration with fumarate or nitrate as oxidants instead of oxygen. IRP of eukaryotes, on the contrary, is unable to serve as iron regulator unless its cluster-binding site (3Cys) is unoccupied and contains free thiols. However, when it acquires a Fe-S cluster as $[4\text{Fe}-4\text{S}]$ protein, it takes

on the function of a cytoplasmic aconitase. Both cytoplasmic and mitochondrial aconitases are only active in their 4Fe form and are inactivated by loss of the unique iron that lacks a Cys ligand. As the 3Fe cluster is relatively stable, it has been proposed that the switch between 4Fe (active) and 3Fe (inactive) enzyme is used in nature to protect the Fe-S cluster from irreversible further oxidation and for metabolic control, because aconitase is necessary for the functioning of the tricarboxylic acid cycle. As nitric oxide reacts with Fe-S clusters, with the main product formed being the dinitrosyl-iron complex (DNIC), NO has to be considered as an alternative messenger in the mentioned sensing pathways. In intact cells, the Fe-S clusters can eventually be rebuilt, as described later. The interrelation of the pathways for sensing iron, oxygen, or its reduction products, and nitric oxide represents an interesting example of crossroads in natural signaling systems.

Methods for Obtaining Information on Fe-S Proteins

While gross information on Fe-S proteins is available from chemical approaches such as analysis for sulfide, iron, protein, and amino acids, spectroscopic methods have furnished a wealth of information on the more detailed and subtle properties of these fascinating, multipurpose tools of nature. Historically, EPR was the first decisive method. It was soon followed by a considerable arsenal of diverse methods. Many of them probe the electronic and magnetic properties of the metal site in various ways that render them complementary to each other and to EPR. The most important of these are Mössbauer, magnetic circular dichroism (MCD), nuclear magnetic resonance (NMR), and electron-nuclear double resonance (ENDOR)

spectroscopies. Other methods, such as resonance Raman and X-ray absorption spectroscopy (EXAFS and XANES), provide specific information relevant to the structural framework of the metal site. Computational approaches have been of great help for unraveling details of the electronic and magnetic structures of Fe-S clusters.

Biogenesis of Iron-Sulfur Proteins

General Overview

The *in vitro* reconstitution of Fe-S clusters on apoproteins, using iron salts, thiols, and inorganic sulfide, was demonstrated in the 1960s. The Fe-S compounds were also synthesized in the absence of protein in order to explore cluster chemistry. However, it was not until the late 1990s that the biosynthesis of Fe-S clusters in a living cell was shown to be a highly evolved process, requiring the assistance of complex assemblies of proteins, which became a major field of interest and experimentation. At present, three different biogenesis systems have been identified. The nitrogen fixation (NIF) system was first discovered from genetic studies for the specialized assembly of the complex Fe-S protein nitrogenase and also occurs in nondiazotrophic ϵ -proteobacteria. The ISC (iron-sulfur cluster) system is a more general assembly machinery present in α -, β -, and γ -proteobacteria as well as in mitochondria of eukaryotes. The most recently discovered system is the SUF (sulfur mobilization) machinery, which is found in a wide range of bacteria including cyanobacteria, archaea, and plastids of plants. In some organisms, the NIF, ISC, or SUF system is responsible for assembly of cellular Fe-S proteins, whereas in other species they are present in parallel, and may be responsible for the assembly of different subsets of Fe-S proteins.

The three systems have in common two proteins. A cysteine desulfurase (NifS, IscS, or SufS) is a pyridoxal-phosphate-dependent enzyme which converts the amino acid Cys to Ala, liberating the sulfur which is covalently bound as an S-sulfide at a conserved Cys residue prior to insertion into the Fe-S cluster. A scaffold protein (NifU, IscU, or SufU), containing Cys residues, serves as a platform for the assembly of Fe-S clusters. This structure is labile and can be transferred to target proteins. In addition, there are iron-transfer proteins, electron-transfer proteins (Fd), and specialized proteins such as chaperones that facilitate the assembly of particular clusters and their stable integration into finished Fe-S proteins.

Biogenesis of Fe-S Proteins in Bacteria

The ISC assembly machinery

In prokaryotes, the operon for the ISC assembly machinery encodes the proteins IscS, IscU, IscA, HscA, HscB, and Fdx. In addition to these proteins directly required for biogenesis, IscR is involved in the regulation of the *isc* gene expression. Biogenesis starts with the production of an S-sulfide sulfur from cysteine by the cysteine desulfurase IscS (Figure 4). The sulfur remains transiently bound to IscS and, upon interaction of IscS with the dimeric form of IscU, the sulfur moiety is transferred to IscU, where it is also bound as a persulfide. The binding of ferrous iron to IscU leads to the formation of a [2Fe-2S] cluster, which then can give rise to the generation

Figure 4 A working model for biosynthesis of Fe-S proteins in bacteria. For details, see text. Abbreviation: pmf, proton motive force.

of a [4Fe-4S] cluster. Thus, IscU provides a scaffold for assembly of iron and sulfide ions. The molecular details of these reactions are still under investigation. IscU interacts with two chaperones, the ATP-dependent Hsp70/DnaK homolog HscA and the Hsp70/DnaJ homolog HscB. The interaction strongly stimulates the ATPase activity of HscA, but the precise function of these two proteins remains to be elucidated. Fe-S cluster assembly depends on the transfer of electrons from the [2Fe-2S] ferredoxin Fdx. The reactions which need the input of electrons are not known yet, but may involve the release of sulfur from cysteine by IscS and the dissociation of the Fe-S cluster from IscU. IscA is thought to function as an alternative scaffold protein to facilitate the assembly of Fe-S clusters. A [2Fe-2S] cluster can be assembled on IscA and subsequently transferred to Fe-S proteins such as Fd.

The bacterial SUF machinery

The existence of a biogenesis system for Fe-S proteins in addition to the ISC assembly machinery has been noted only recently. When the *isc* operon is deleted in *Escherichia coli*, Fe-S proteins are assembled at an efficiency of only 2–10% of that in wild-type cells. The residual assembly activity is due to the *suf* (mobilization of sulfur) operon which contains the proteins SufA, SufB, SufC, SufD, SufS, and SufE. Many organisms contain only a subset of the *suf* genes. Overexpression of the *suf* gene cluster can restore Fe-S protein assembly in an *isc* deletion mutant. The *suf* operon is induced under iron-limiting conditions and repressed by the iron-sensing repressor protein Fur. Further, the *suf* operon is regulated by the transcription factor OxyR that senses oxidative stress conditions. This suggests that the SUF system is crucial under iron-limiting and oxidative stress conditions. The Suf proteins, homologs of Fdx and NifU, and an Fdx reductase are also present in apicoplasts, a plastid-like organelle of Apicomplexa such as *Plasmodium* and *Toxoplasma*.

SufS and SufA are homologs of IscS and IscA, respectively, and may serve similar functions in liberating sulfur from cysteine, in scaffolding, and in cluster assembly. SufC is an atypical ATPase which forms a complex with SufB and SufD. SufE accepts sulfur from SufS and acts synergistically with the SufBCD

complex to stimulate the cysteine desulfurase activity of SufS. This regulation of SufS activity may be important for limiting sulfur release during oxidative stress conditions. In addition, SufS has been assigned a function as a selenocysteine lyase in *E. coli*.

Assembly of superclusters in nitrogenase and hydrogenase

The iron–molybdenum cofactor (FeMo-co) in nitrogenase and the H cluster in FeFe-hydrogenase are each located in a cavity in the enzyme, bound to the protein by just one Cys. Each is constructed in a scaffold protein by a series of accessory proteins and chaperones before transfer to the finished enzyme. Central components in the biosynthesis of FeMo-co are NifN and NifE, which form a hetero-tetramer and serve as a scaffold for cluster assembly before transfer to NifKD apoproteins. Further components needed for FeMo-co assembly are the *nif* operon-encoded proteins NifQ (Mo processing), NifV (homocitrate synthase), NifB (sulfur and iron donor), as well as NifH and NifX, the functions of which are unknown. Studies on nitrogen-fixing bacteria have identified the *nif* (nitrogen fixation) operon as being responsible for maturation of the complex Fe–S protein nitrogenase. This enzyme consists of two oxygen-labile metalloproteins, the MoFe protein (encoded by NifKD) and the Fe protein (NifH). The latter contains a [4Fe–4S] cluster, bound between two subunits, whereas the MoFe protein is associated with two unique superclusters: the P cluster and the FeMo-co (Figure 2). The *nif* operon-encoded proteins NifS and NifU are involved in cluster biosynthesis by performing similar functions as their homologs IscS and IscU, respectively. The N terminus of NifU is homologous to IscU and provides a scaffold for assembly of transiently bound clusters, whereas the middle part of NifU contains a permanent [2Fe–2S] cluster that may carry out a redox function. Further, a homolog of IscA termed NifHscA is thought to be an alternative scaffold for cluster assembly. For FeFe-hydrogenase, the 2Fe subcluster of the H cluster is synthesized on HydF from a [2Fe–2S] cluster framework in a process requiring guanosine triphosphate (GTP) and two AdoMet radical proteins, HydE and HydG, before being transferred to the catalytic subunit HydA.

Biogenesis of Fe–S Proteins in Eukaryotes

The Mitochondrial Fe–S Cluster Assembly Machinery

In eukaryotes, mitochondria are central for biogenesis of cellular Fe–S proteins. Some eukaryotic protists, which lack functioning mitochondria, have mitosomes, intracellular organelles that contain the machinery for Fe–S cluster assembly. Loss of the ability to assemble Fe–S clusters is generally lethal to the cell. A number of inherited diseases are associated with defects in the system, notably the neurodegenerative disease Friedreich's ataxia, which is associated with a defect in frataxin. In keeping with their bacterial origin, these organelles contain homologs of the bacterial ISC and NIF machinery. All proteins of the mitochondrial assembly machinery are encoded by nuclear DNA and are imported after translation in the cytosol. The mitochondrial ISC assembly machinery comprises more proteins than in bacteria, though the underlying mechanistic principles are analogous. For instance, the cysteine desulfurase Nfs1 and the two highly homologous proteins, Isu1 and Isu2, execute similar

Figure 5 A working model for biosynthesis of Fe–S proteins in yeast. For details, see text. Abbreviation: pmf, proton motive force.

functions in elemental sulfur production and scaffolding as bacterial IscS and IscU, respectively (Figure 3). Formation of the transiently bound Fe–S cluster on the Isu proteins depends on the Fd reductase Arh1 and the Fd Yah1, which form an electron transfer chain using reduced nicotinamide-adenine dinucleotide (NADH) as a reducing agent. In addition, Yfh1, a homolog of frataxin, acts as an iron donor during Fe–S cluster synthesis by directly interacting with the Isu/Nfs1 complex. The dissociation of the transiently bound Fe–S cluster from the Isu proteins and/or its insertion into apoproteins requires the mitochondrial glutaredoxin Grx5 and the two chaperones Ssq1 and Jac1 (Figure 5). The IscA homologs Isa1 and Isa2 provide an Isu protein-independent scaffolding function for the assembly of Fe–S clusters. Nfu1 genetically interacts with Ssq1 and Isu1, but its biochemical role in mitochondrial Fe–S protein assembly is not understood to date.

Biogenesis of Fe–S Proteins in Chloroplasts

In plant cells, chloroplasts contain their own assembly machinery, independent of the machinery in mitochondria. Cyanobacteria, which are believed to be the evolutionary ancestors of chloroplasts, contain several homologs of the ISC assembly machinery and also the SUF system. In chloroplasts, a NifS homolog, CpNifS, and an Fe–S-binding P-loop NTPase, HCF101, have been identified as the cysteine desulfurase and scaffold proteins of this system.

The Cytosolic CIA System

The mitochondrial ISC assembly machinery not only is responsible for the assembly of mitochondrial Fe–S proteins but also plays an essential function in the maturation of Fe–S proteins outside mitochondria. To date, four components have been identified that are specifically needed for maturation of

extra-mitochondrial, but not of mitochondrial Fe–S proteins (Figure 5). The first-known protein of the so-called ISC export machinery is the mitochondrial ABC transporter Atm1. The other components are the sulfhydryl oxidase Erv1 of the intermembrane space and glutathione (GSH). Since virtually all components of the mitochondrial ISC assembly machinery are involved in the maturation of extra-mitochondrial Fe–S proteins, it is assumed that Atm1 exports a Fe–S cluster or a derivative thereof to the cytosol for transfer onto apoproteins. Mutation of the human homolog of Atm1, termed ABC7, gives rise to the iron storage disease X-linked sideroblastic anemia and cerebellar ataxia (XLSA/A). Finally, biogenesis of cytosolic Fe–S proteins requires Cfd1, a cytosolic P-loop ATPase that is conserved in all eukaryotes. The protein may assist in Fe–S cluster insertion into cytosolic apoproteins.

Mitochondria appear to be essential organelles because they perform crucial steps in the biosynthesis of cytosolic Fe–S proteins. Many components of the ISC machineries are essential for viability of yeast cells (e.g., Nfs1, Yah1, Arh1, Jac1, Erv1, and Cfd1) which demonstrates the importance of Fe–S protein biogenesis. Outside of the mitochondria, four highly conserved proteins (Cfd1, Nbp35, Nar1, and Cia1) have been identified as members of the cytosolic [Fe–S] protein assembly machinery. The structure of Nar1 is similar to that of the FeFe-hydrogenases, although it does not contain the H-cluster. The soluble P-loop NTPases Cfd1 and Nbp35 function as a scaffold for assembly of labile [Fe–S] clusters, which can be rapidly transferred and incorporated into target [Fe–S] apoproteins in a Nar1- and Cia1-dependent fashion.

Glossary

Apoptosis Orderly process of programmed cell death by which a cell commits suicide.

Coiled coil Tertiary structure of a protein motif mediating oligomerization in which two alpha helices wrap around each other forming a hydrophobic core with characteristic interdigitation of side chains between neighboring helices, known as ‘knob-in-hole packing’.

Complex epithelia One to several layers of cells in which nuclei are present on several planes covering either internal or external surfaces of the body.

Desmosome Junction formed between adjacent cells in order to form a tissue.

Hemidesmosome Junction that anchors cells to the basement membrane.

Intermediate filaments Nonpolar, 10-nm-wide filamentous proteins of the cytoskeleton that provide structural support to the cell.

Pilosebaceous unit Comprised of a hair follicle, sebaceous gland attached to it, and arrector pili muscle.

Simple epithelium A single layer of cells attached to a basal lamina, in which all nuclei are aligned in a single plane often covering an internal surface of the body.

Keratins are among the most abundant proteins in epithelial cells, in which they occur as a cytoplasmic network of 10-nm-wide intermediate filaments. Keratin proteins are encoded by a large multigene family in mammals, with 54 individual genes that can be readily partitioned into two major sequence types. A strict requirement for the heteropolymerization of types I and II keratin proteins during filament assembly underlies the pairwise transcriptional regulation of keratin genes. Modulation of keratin expression also depends upon both the type and stage of differentiation in epithelia. A major function fulfilled by keratin filaments is to act as a resilient yet pliable scaffold, which endows epithelial cells with the ability to sustain mechanical and nonmechanical stresses. Reflecting a partial or complete loss of this crucial scaffolding role, genetic mutations altering the coding sequence of keratins account for a large number of epithelial fragility disorders. Several additional roles for keratin proteins, affecting cell growth, migration, programmed cell death, and response to stresses, are manifested in a sequence- and context-dependent fashion and play key roles in normal physiology and in disease.

Keratin Classification

Keratins belong to the superfamily of intermediate filament (IF)-forming proteins. They are heterogeneous in size

(40–72 kDa) and charge ($pI \sim 4.7$ –8.4), and notoriously insoluble. The original keratin nomenclature, devised in 1982 by Roland Moll, Werner Franke, and their colleagues, was based upon protein separation by both charge and size via two-dimensional electrophoresis. A revised nomenclature was produced in 2006 to accommodate a large number of novel keratins (uncovered mainly through whole genome sequencing efforts) while complying with the human and mouse genome nomenclature committees. Type I keratins ($n=28$; [Figure 1](#)) tend to be smaller (40–64 kDa) and acidic ($pI \sim 4.7$ –6.1) compared to the larger (52–68 kDa) and basic–neutral ($pI \sim 5.4$ –8.4) type II keratins ($n=26$; [Figure 1](#)). Homology at both the protein (see [Figure 1\(a\)](#)) or DNA sequence levels, as well as gene substructure (number and position of introns), readily confirms the partitioning of keratin genes and proteins into type I and II IF sequences.

Keratin Gene Clusters Reflect Tissue Expression: Implications for Keratin Evolution

The coordinated regulation of two distinct types of keratin genes, along with the obligatory heteropolymerization of their products to form 10-nm-wide filaments, is present as far back as primitive chordates. In *Homo sapiens*, functional type I and type II keratin genes are clustered on the long arms of

Figure 1 The human keratin family c. 2011. (a) Comparison of the primary structure of human keratins using the publicly available ClustalW and TreeView softwares. Sequence relatedness is inversely correlated with the length of the lines connecting the various sequences as well as the number and position of branch points. This comparison makes use of the sequences from the head and central rod domain for each keratin. Two major branches are seen in this tree, corresponding exactly to the known partitioning of keratin genes into type I and type II sequences. Beyond this dichotomy each subtype is further segregated into major subgroupings. (b) Location and organization of type I and type II keratin genes in the human genome. All functional type I keratin genes, except Krt18, are clustered on the long arm of human chromosome 17, while all functional type II keratin genes are located on the long arm of chromosome 12. Krt18, at type I gene, is located at the telomeric (Tel) boundary of the type II gene cluster. The suffix P identifies nonfunctional keratin pseudogenes. As highlighted by the color code used in frames (a) and (b), individual type I and type II keratin genes belonging to the same subgroup, based on the primary structure of their protein products, tend to be clustered in the genome. Moreover, highly homologous keratin proteins (e.g., Krt5 and Krt6 paralogs; also, Krt14, Krt16, and Krt17) are often encoded by neighboring genes, emphasizing the primary role of gene duplication in generating keratin diversity. These features of the keratin family are virtually identical in mouse (not shown).

chromosomes 17 and 12, respectively (Figures 1(b) and 1(c)). There is a notable exception to this principle, in that the type I keratin 18 (Krt18) locus is located next to Krt8 at the telomeric boundary of the type II cluster (Figure 1). Krt8 and Krt18 exhibit a tight coregulation in both embryonic and adult simple epithelia, and likely are direct descendants of the ancestral pair of keratin genes. The key molecular features of individual keratin genes (e.g., size and number of introns/exons) and those of the genomic clusters they form (e.g., transcriptional orientation and position relative to other family members) are highly conserved in human and mouse, and in many other species of mammals as well. This conservation has direct implications for the evolution of keratin genes and points to the

existence of locus control elements simultaneously affecting the regulation of several neighboring genes.

Comparing the primary structure of human keratin proteins also reveals the existence of distinct subfamilies within each of the two keratin types (Figure 1(a)), and provides additional insight into the mechanisms presiding over their evolution. Groupings of individual genes within each of the two major clusters tend to reflect expression in related types of epithelial cells or tissues. This situation applies for most genes expressed in simple epithelia (Krt7, Krt8, Krt18, and Krt20), soft complex epithelia (e.g., Krt1–Krt6; Krt9–Krt17), hard epithelia such as hair shaft and nail (Krt31–38; Krt81–86), and even the highly restricted inner root sheath (IRS)

compartment of hair follicles (Krt25–Krt28; Krt71–Krt74). A small subset of keratin genes exhibits a mixed regulation in two or more types of epithelia (e.g., Krt19 and Krt80). In addition to these intriguing features, the clustering of keratin genes is mirrored by a corresponding clustering of related protein products as revealed by phylogenetic analysis. This striking equivalence, highlighted by the color scheme employed in [Figure 1](#), implies a hierarchical pattern of gene duplication and specialization during evolution.

Keratin Proteins Form the Intermediate Filament Network of Epithelial Cells

Features of Keratin Proteins

Despite sequence differences, all keratins display the tripartite domain structure that is typical of IF-forming proteins ([Figure 2\(a\)](#)). The central domain consists of an extended α -helix featuring long-range heptad repeats that mediate coiled-coil dimerization. This rod domain is invariably 310 amino acids long and is flanked by highly variable sequences at the N-terminal head and C-terminal tail domains. Neither terminal domain exhibits known functional motifs other than the poorly understood glycine loops seen in epidermal keratins. The head and tail domains are protease- and kinase-accessible and, thus, are exposed at the surface of filaments, where they can foster interactions with neighboring filaments, other proteins, as well as serve as substrates for posttranslational modifications involved in their regulation. Given the marked heterogeneity observed in both their size and primary structure, the head and tail domains are poised to impact the regulation and function of individual keratin proteins *in vivo*.

Keratin Proteins Self-Assemble into 10–12-nm-Wide Filaments

The central rod domain of keratins is the main determinant of polymerization, with additional contributions provided by the head domain. By contrast, the tail domain appears to be largely dispensable for 10-nm filament assembly. Keratin polymerization begins with the formation of heterodimers in which the α -helical rod domains of type I and II keratins are aligned in parallel and perfect register. These heterodimers then interact along their lateral surfaces and then in an end-to-end fashion to give rise to the 10-nm-wide filaments. The extraordinary stability of keratin heterodimers (they resist 9 M urea!) and heterotetramers underscores the tightness of the interactions between type I and type II rod domains. Not surprisingly, most of the intracellular pool of keratin proteins (>95%) is in the polymerized form.

Organization and Regulation of Keratin Filaments *In Vivo*

The abundance and intracellular organization of keratin IFs *in vivo* varies according to the epithelium considered. Keratins are particularly abundant (from ~15% to ~80% of total cellular proteins) in surface-exposed stratified epithelia (e.g., epidermis, oral mucosa, cornea, etc.). In cells of such tissues, keratin IFs are organized in a pan-cytoplasmic network extending from the surface of the nucleus to the cytoplasmic periphery, where

they associate with membrane-spanning cell–cell or cell–matrix attachment complexes such as desmosomes ([Figure 2\(c\)](#)) and hemidesmosomes. In simple epithelia (e.g., liver, gut, pancreas, etc.), keratins remain a major fraction of proteins even though they are less abundant (from 1% to 5 % of total cellular proteins). Such tissues are made up of polarized epithelial cells that often contain asymmetrically organized keratin IFs, concentrated mostly at the cytoplasmic periphery and particularly at the apical pole. A number of associated proteins interact with and contribute to the organization of keratin IFs in these various settings. Some directly promote the bundling of keratin IFs (e.g., filaggrin and trichohyalin), their association with microtubules and microfilaments (e.g., plectin and bullous pemphigoid antigen (BPAG) isoforms), and/or with desmosomes or hemidesmosomes (desmoplakin, plakophilin, BPAG isoforms, etc.).

Keratin Posttranslational Modification

The organization of keratin filaments *in vivo* is also regulated through phosphorylation. All keratin proteins are phosphoproteins. Their phosphorylation by a variety of kinases occurs in a very dynamic and reversible fashion, usually on Ser/Thr residues, and involves multiple sites on the nonhelical head domain and, to a lesser extent, on the tail domain. Circumstances in which keratin IFs are reorganized in a rapid fashion, such as during mitosis or cellular stress, invariably correlates with increased phosphorylation of specific residues located in the end domains. The head domains of at least some keratins are also substrates for ubiquitination (which mediates their degradation) and O-glycosylation (whose significance has yet to be ascertained). As is the case for microtubules and actin microfilaments, the assembly and organization of keratin IFs is thus regulated through a variety of mechanisms in epithelial cells, and undoubtedly represents a key determinant of their function *in vivo*.

Keratin Gene Expression Mirrors Epithelial Differentiation: The Case of Skin

Skin provides a beautiful example of the tight relationship that exists between keratin gene regulation and epithelial differentiation and function. More than half of all keratin genes are expressed in mature mammalian skin tissue ([Figure 2](#) and [Table 1](#)). The architectural complexity of adult skin epithelia is achieved through a temporally and spatially regulated sequence of simple decisions, resulting in progressive restriction of fate determination and reflected by specific changes in keratin gene regulation. In the clinical setting, keratin typing is often exploited in diagnosing cancer type, its differentiation status (and therefore prognosis), as well as the origin of the cells forming metastatic foci. This strategy is also applied for diseases other than cancer.

Keratin Gene Expression in Thin Epidermis

In thin epidermis, mitotically active cells of the basal layer act as progenitors, and consistently express Krt5 and Krt14 as their main keratin pair ([Figure 2\(f\)](#)), along with lower levels of Krt15. Onset of differentiation coincides with the appearance

Figure 2 Attributes, differential regulation, and disease association of keratin. (a) Schematic representation of the tripartite domain structure shared by all keratin and other intermediate filament proteins. A central α -helical rod domain acts as the major determinant of self-assembly and is flanked by nonhelical head and tail domains at the N- and C-termini, respectively. The ends of the rod domain contain 15–20-amino-acid regions (yellow) highly conserved among all intermediate filaments. (b) Visualization of filaments, reconstituted *in vitro* from purified K5 and K14, by negative staining and electron microscopy. scale = 125 nm. (c) Triple-labeling for keratin (red chromophore) and desmoplakin, a desmosome component (green chromophore) and DNA (blue chromophore), by indirect immunofluorescence of epidermal cells in culture. Keratin filaments are organized in a network that spans the entire cytoplasm and are attached at points of desmosomal cell–cell contacts (arrowheads) between cells. Scale = $\sim 30 \mu\text{m}$. N, nucleus. (d) Ultrastructure of the cytoplasm of epidermal cells in primary culture, as visualized by transmission electron microscopy. Keratin filaments are abundant and tend to be organized in large bundles of loosely packed filaments in the cytoplasm. Scale = $2.5 \mu\text{m}$. (e) Histological cross-section of resin-embedded human trunk epidermis, revealing the basal (B), spinous (S), granular (G), and stratum corneum (C) compartments. Bar equals $\sim 50 \mu\text{m}$. N, nucleus. (f, g) Differential distribution of keratin epitopes on human skin tissue cross-sections (similar to frame (e)) as visualized by an antibody-based detection method. K14 occurs in the basal layer (g), where the epidermal progenitor cells reside. K10, on the other hand, is primarily concentrated in the differentiating, suprabasal layers of epidermis. Dashed line indicates the basal lamina. Scale = $\sim 100 \mu\text{m}$. (h) Ultrastructure of the boundary between the basal and suprabasal cells in mouse trunk epidermis, as seen by routine transmission electron microscopy. The sample, from which this micrograph was taken, is oriented in the same manner as frame (e). Organization of keratin filaments as loose bundles (see brackets in basal cell) correlates with the expression of K5–K14 in basal cells, whereas the formation of much denser and electron-dense filament bundles (see brackets in spinous cell) reflects the onset of K1–K10 expression in early differentiating cells. Arrowheads point to desmosomes connecting the two cells. Scale = $1 \mu\text{m}$. N, nucleus. (i) Newborn mouse littermates. The top mouse is transgenic (Tg) and expresses a mutated form of K14 in its epidermis. Unlike the control pup below (Wt), this transgenic newborn shows extensive blistering of its front paws (arrows). (j, k) Hematoxylin/eosin-stained histological cross-section through paraffin-embedded newborn mouse skin (similar to those shown in frame (i)). Compared to the intact skin of a control littermate ((k), Wt), the epidermis of the K14 mutant expressing transgenic pup ((j) Tg) shows intra-epidermal cleavage at the level of the basal layer, where the mutant keratin is expressed (see opposing arrows). Scale = $100 \mu\text{m}$. (l) Leg skin in a patient suffering from the Dowling–Meara (severe) form of epidermolysis bullosa simplex. Characteristic of this severe variant of this disease, several skin blisters are grouped in a herpetiform fashion.

Table 1 Distribution of keratins in the major compartments of skin epithelia

<i>Skin compartment</i>	<i>Cell type</i>	<i>Keratin expression (mRNA level)</i>
Interfollicular epidermis	Basal keratinocytes	Krt5, Krt14; also, Krt15
	Early differentiating keratinocytes	Krt1, Krt10
	Late differentiating keratinocytes	Krt2
	Merkel cells (in basal layer)	Krt8, Krt18, Krt20
Palmar/plantar epidermis	Basal keratinocytes	Krt5, Krt14; also Krt15, Krt17, Krt19
	Early differentiating keratinocytes	Krt1, Krt9, Krt10; Krt6, Krt16
	Late differentiating keratinocytes	Krt2
Hair follicles	Outer root sheath	Krt5, Krt14, Krt17; also, Krt15, Krt19
	Companion layer	Krt6a, Krt16 and Krt75, Krt17
	Inner root sheath	Krt25–28; Krt71–74; also, Krt7
	Hair shaft: cuticle and cortex	Primarily Krt31–38; Krt81–86
	Hair shaft: medulla	Krt17, Krt75; several others
	Glandular epithelium	Krt8, Krt18, Krt14; others?
Sebaceous glands (apocrine)	Cambial cells	Krt5, Krt14, Krt17
Sweat glands (eccrine)	Glandular epithelium	Krt8, Krt18; others?
	Myoepithelium	Krt5, Krt7, Krt14, Krt17
Nail	Duct	Krt5, Krt14; Krt7, Krt17; Krt6, Krt16
	Matrix	Krt5, Krt14, Krt17
	Nail plate	Primarily Krt31–38; Krt81–86
	Nail bed	Krt5, Krt14; Krt7, Krt17; Krt6, Krt16
	Proximal nail fold	Krt5, Krt14; Krt1, Krt10; Krt6, Krt16
	Hyponychium (upper layers)	Krt5, Krt14; Krt17; Krt6, Krt16

of the Krt1/Krt10 pair through a robust transcriptional induction that occurs at the expense of Krt5/Krt14. Accordingly, Krt1/Krt10 proteins are readily detectable in the lowermost suprabasal layer of epidermis (**Figure 2(g)**). The appearance of Krt1 and Krt10 correlates with a sudden and dramatic shift in the organization of cytoplasmic keratin filaments, which now exhibit significant bundling (**Figure 2(h)**). Another type II keratin gene, Krt2e, is expressed at a later stage of differentiation.

Keratin Gene Expression in Thick Epidermis

The epidermis of palm and sole skin is significantly thicker, owing to its specialization for resisting larger amounts of stress. This function is reflected in its architecture of alternating stripes of primary and secondary ridges, and specific changes in keratin expression. In the thick, stress-bearing, primary ridges, the major differentiation-specific type I Krt9 is presumed to foster a more resilient cytoskeleton. In the thinner secondary ridges, post-mitotic cells preferentially express the type II Krt6a and type I Krt16 and Krt17. Relative to Krt1, Krt9, and Krt10, the properties of Krt6a, Krt16, and Krt17 are believed to foster greater cellular pliability, thereby providing flexible hinge regions in-between the more rigid Krt1/Krt9-rich primary ridges. While it remains to be supported by experimentation, this attractive notion is consistent with the dramatic upregulation of K6a, K6b, K16, and K17 that occurs in keratinocytes recruited from wound margins to participate in the restoration of the epidermal barrier following injury.

Keratin Gene Expression in Hair Follicles

Consistent with its greater complexity, a larger number of keratin genes are transcribed in the pilosebaceous unit (**Table 1**).

A mature hair follicle houses eight distinct epithelial layers segregated into three histological compartments organized in concentric circles along its main axis. These compartments are, from inside out, the hair shaft proper; the IRS; and the outer root sheath (ORS), an epithelium that wraps around the follicle and is contiguous with the epidermis. The regulation of the >27 keratin genes expressed in hair follicles is detailed in **Table 1**. Key features are highlighted here. The Krt31–Krt38 and Krt81–Krt86 genes are unique to the hair shaft and related hard epithelia (e.g., nail; filiform papillae of the tongue). These keratin genes exhibit a stage-specific regulation during the differentiation of matrix progenitors in the bulb region to hair cortex keratinocytes. The cysteine-rich head and tail domains of the hard keratin proteins form disulfide bridges which, along with the γ -glutamyl cross-links catalyzed by transglutaminases, foster the organization of large bundles of densely packed keratin filaments. This organization endows hair (and nail) with its unique structural features, shape, and resilience. Krt25–28 and Krt71–74 are found in the IRS compartment. The ORS epithelium, on the other hand, expresses several of the keratins genes expressed in the epidermis, with the notable exception of the differentiation-specific Krt1, Krt2e, and Krt10 (**Table 1**). By the time an epidermal or hair cortex keratinocyte has completed differentiation, more than 80% of its protein content is keratin. This extreme situation is reminiscent of globin gene expression in erythrocytes, another highly specialized cell type, and underscores the fundamental importance of keratin proteins to surface epithelia.

Functions of Keratin Filaments

Structural Support

The properties typifying keratin filaments collectively point to an important structural role. Evidence for this function came from

Table 2 Representative skin disorders associated with mutations in keratin genes

<i>Disease</i>	<i>Main target tissue</i>	<i>Gene mutated</i>
Epidermolysis bullosa simplex	Basal cells/epidermis	Krt5, Krt14
Epidermolytic hyperkeratosis	Differ. cells/epidermis	Krt1, Krt10
Ichthyosis bullosa of Siemens	Differ. cells/epidermis	Krt2
Meesman's corneal dystrophy	Cornea	Krt3, Krt12
Monilethrix	Hair cortex	Krt81, Krt86
Oral white sponge nevus	Oral mucosa	Krt4, Krt13
Pachyonychia congenita		
Type 1 (Jadhasson–Lewandowsky)	Nail; other appendages	Krt6a, Krt16
Type 2 (Jackson–Lawler)	Nail; other appendages	Krt6b, Krt17
Palmoplantar keratoderma		
Epidermolytic	Palmar/plantar epidermis	Krt9
Nonepidermolytic	Palmar/plantar epidermis	Krt1, Krt16
Steatocystoma multiplex	Sebaceous glands	Krt17

transgenic mouse studies in which a mutated form of K14 capable of dominantly disrupting filament assembly and organization was targeted to the basal layer of epidermis *in vivo*. Unlike controls, mutant-expressing animals exhibited massive intracellular lysis of the basal cells in response to modest mechanical trauma to the skin (**Figures 2(i)–2(k)**). This mouse phenotype mimicked key aspects of a group of dominantly inherited epidermal disorders known as ‘epidermolysis bullosa simplex’ (EBS, **Figure 2(l)**), and it was shown shortly thereafter that the human condition arises from mutations in either Krt5 or Krt14. EBS turned out to be a very useful paradigm. We now know that keratin IFs fulfill a similar function in all complex epithelia, ranging from the surface of the eye (cornea) to hair tissue. *In vitro* studies showed that keratin IFs exhibit unique viscoelastic properties that support their involvement in a structural capacity, and that disease-causing mutations significantly decrease the strength of keratin assemblies subject to mechanical strain. Likewise, biophysical studies of live cells in culture showed that keratin IFs account for a substantial fraction of their viscoelastic properties, and that disrupting keratin cytoplasmic organization causes cells to soften considerably. Demonstration of a structural support role has been comparatively more difficult for simple epithelial tissues, but strong evidence to that effect now exists for liver hepatocytes as well as trophoblast giant cells.

Scaffolding Components of Signaling Pathways and Other Functions

Transgenic mouse studies that focused on adult liver and extra-embryonic tissue revealed that simple epithelial keratins 8/18 play an important cytoprotective role against chemical insults and in modulating the response to pro-apoptotic signals. In liver hepatocytes, the function of cytoprotection requires phosphorylation of K8/K18. In regard to apoptosis, studies showed that K8/K18 filaments can bind to, and either organize or sequester, key intracellular effectors of the signaling machinery downstream from engagement of the tumor necrosis factor- α (TNF- α) and fas receptors. Of note, the presence of K17 is also required for the survival of matrix epithelial cells in mature hair follicles. It appears likely that keratin IFs will be found to influence additional basic metabolic processes in the cell. In that regard, recent studies have shown that an intact K8/K18 filament network is required for the proper sorting of specific membrane proteins in polarized

simple epithelial cells. Determining how nonpolar assemblies are adapted to foster spatial organization in the cell promises to reveal additional keratin properties and functions.

Keratin Involvement in Disease

The role of keratin mutations in causing several epidermal, oral, ocular and hair-related diseases is well established (see **Table 2**, which emphasizes skin diseases). These diseases are genetically well defined and typically inherited in an autosomal-dominant fashion, although recessive inheritance is occasionally seen. The vast majority of genetic lesions consist of missense mutations, although premature stop codons, small deletions, and mutations affecting messenger RNA (mRNA) splicing occur with some frequency. In general, disease severity correlates with the location and nature of the mutation within the keratin backbone. A keratin mutation database is being maintained at the Centre for Molecular Medicine and the Bioinformatics Institute in Singapore and can be accessed online (Human Intermediate Filament Database, see section Relevant Website).

For most of the disorders listed in **Table 2**, mutations are causative for the disease and act through their ability to compromise the role of keratin IFs toward structural support. Mutations causing severe outcomes tend to affect amino acid residues that are highly conserved at either end of the central rod domain (**Figure 1(a)**), and often lead to the appearance of large aggregates of mispolymerized keratins in the cytoplasm of affected cells. In such instances, the aggregates appear to exacerbate the effect of the loss of a functional keratin IF network, and contribute to disease pathogenesis. Other types of mutations may also elicit alternative mechanisms of disease pathogenesis. Examples include mutations that could either affect keratin degradation during apoptosis or directly modulate keratin phosphorylation by introducing or removing a potential phosphorylation site. In contrast to other keratins, mutations affecting the simple epithelial keratins K8/K18 appear to predispose to, rather than cause disease *per se*. Again, this notion is supported by studies involving transgenic mice. Many of the diseases listed in **Table 2** are characterized by a clinical heterogeneity that cannot be entirely accounted for through the position and nature of the mutation along the keratin chain. For instance, the same missense allele of K17, Arg₉₄→Cys, can cause either type 2 Pachyonychia

Congenita (which affects primarily the nail) or Steatocystoma Multiplex (a glandular disorder with minimal if any nail alterations) in different kindreds. Together with studies involving gene manipulation in mice, this finding points to a sometimes dramatic impact of the genetic background on disease expression.

Glossary

Centromere The primary constriction of a mitotic chromosome that connects two sister chromatids.

Kinetochores The proteinaceous structure that assembles onto each side of the centromere, allowing for chromosome

attachment to and movement on microtubules of the mitotic spindle.

Microtubule Polar, cylindrical polymers formed from ~13 laterally associated protofilaments of $\alpha\beta$ -tubulin.

Kinesins constitute a large evolutionarily conserved superfamily of enzymes that are fundamentally important for many aspects of unicellular and multicellular life. These molecular motors bind microtubules, which are polar cylindrical polymers of $\alpha\beta$ -tubulin that are important for spatial organization within the cell. Kinesin-1, the first kinesin to be isolated, was purified by taking advantage of its ability to couple ATP hydrolysis to translocation along microtubules. This activity underlies its ability to drive long-range transport of cellular cargos from one region of a cell to another. Sequences homologous to the catalytic domain responsible for the motor activity of Kinesin-1 have been discovered in a large number of proteins, and the complete genomic complement of kinesins is known for eukaryotes with fully sequenced genomes.

Although motility was the defining activity of kinesins, recent work has revealed that the catalytic domain is used in a subset of kinesins to drive microtubule disassembly rather than translocation. Physiologically, the regulation of microtubule dynamics by kinesins is likely to be of great significance in cellular organization, division, and differentiation. Here, we first briefly review the work that led to the recognition of specific kinesins acting as microtubule disassembly enzymes. We then discuss progress toward understanding the mechanism by which the catalytic domain is used to drive microtubule depolymerization and finally comment on the physiological relevance of this nonmotile activity.

Microtubule Dynamics Regulation in Cells – the Need for Depolymerases

In vitro, microtubules exhibit dynamic instability, a steady-state behavior wherein individual microtubule ends will interconvert between assembly and disassembly. The term catastrophe describes the transition from assembly to shrinkage, whereas rescue describes the transition from disassembly to assembly. In principle, dynamic instability permits the cell to rapidly reorganize its microtubule array by changing the number of microtubule nucleating sites or altering the frequency of the transitions between assembly and disassembly without changing the concentration of tubulin dimers via protein synthesis.

Early landmark studies of microtubules at the edges of live cells recorded similar stochastic transitions between assembly and disassembly which were independent of the behavior of neighboring microtubules. However, more recent studies, where the assembling tips of live microtubules are reported using '+TIP' proteins, enable microtubule polymerization to be scored at any position within the living cell. These studies reveal a distinctly different picture of microtubule turnover in cells. Consistent with the observation that microtubules assembled *in vitro* from tubulin purified from non-neuronal sources is considerably less dynamic than tubulin purified from brain, we now know that microtubules in cultured epithelial cells assemble persistently from the centrosome to the cell margin. Only upon reaching the cell margin are microtubule ends likely to transition between phases of shortening, assembly, and paused states. This behavior is accomplished by a host of assembly and disassembly factors that camouflage the intrinsic dynamic instability of microtubules.

Persistent assembly of microtubules is under the control of proteins such as the +TIP EB1 that, in addition to its own microtubule assembly promoting activity, can recruit microtubule regulatory proteins to the microtubule tip. Dynamic instability of microtubules in cells is suppressed by assembly factors and must, in turn, be reversed by disassembly factors. This service is performed, to a large extent, by two key kinesin protein families: the Kinesin-13 family of microtubule depolymerizers and, potentially, the Kinesin-8 family (Figure 1).

The most potent and well-characterized of the Kinesin-13s is MCAK/Kif2C, which removes tubulin dimers in an ATP-dependent fashion from the ends of artificially stabilized microtubules, such as those assembled with the GTP analog guanosine-5'-[(α , β)-methylene]triphosphate (GMP-CPP) (Figure 2(a)). For physiological microtubules that are intrinsically unstable, MCAK/Kif2C triggers transitions from assembly to disassembly (catastrophe) without altering either the rate of disassembly or assembly itself. Although MCAK/Kif2C strongly catalyzes catastrophes on microtubules in isolation; its activity is significantly enhanced both in cells and *in vitro* by recruitment to microtubule ends by EB-family members. Notably, of the three mammalian Kinesin-13 family members, only MCAK/Kif2C is directly recruited to microtubule ends by EB proteins.

Figure 1 Domain structure of the microtubule-depolymerizing kinesins. Proteins containing a kinesin-like catalytic domain (green) are defined as members of the kinesin superfamily. Motors are oriented with their N-termini positioned leftward. Kinesin-13s contain an internally located motor domain that is sandwiched by a globular N-terminus (ochre) and a C-terminal coiled-coil (black). Kinesin-8s are N-terminal kinesins, with a C-terminal tail (red) that is linked to the motor domain by a coiled coil. Kinesin-14s are C-terminal kinesins with a tail domain located at the N-terminus.

Figure 2 Enzymology of microtubule-depolymerizing kinesins. (a) Kinesin-13 family. MCAK/Kif2C (Kinesin-13) can diffuse bidirectionally on the microtubule lattice in the absence of nucleotide hydrolysis. Upon encountering either the plus or minus end of the microtubule, the motor can form a high-affinity complex with the bent protofilament in an ATP-bound state. The motor removes a tubulin dimer from the microtubule coordinately with the attainment of the transition state for ATP hydrolysis. Hydrolysis culminates in the release of the free tubulin dimer from the motor itself recycling the motor for another round of tubulin removal. Kinesin-13 motors can disassemble microtubules from either end. (b) Kinesin-8 family. Kinesin-8 motors utilize the energy of ATP hydrolysis to translocate many hundreds of steps toward the plus end of the microtubule without detaching from the polymer. Motors pause at the plus end and may suppress dynamics there via an unknown mechanism. In the case of Kip3 (*S. cerevisiae*), the arrival of another motor triggers the loss of the terminal motor, and its associated tubulin dimer, leading to preferential disassembly of the plus end. It is not known how ATP hydrolysis contributes to this flux-dependent tubulin removal.

The Kinesin-8s also significantly influence microtubule dynamics. On stabilized microtubules *in vitro*, Kinesin-8s will walk unidirectionally toward the plus end of the microtubule in an ATP-dependent fashion where they proceed to disassemble the microtubule from the plus end only (Figure 2(b)). In cells, the effects of these kinesins are more equivocal as they appear to suppress both assembly and disassembly of microtubules.

This leads to a general picture of microtubule turnover in cells that is dependent on Kinesin-8s, Kinesin-13s, and

numerous other regulatory factors. While dynamic instability is a key property that describes the fundamental behavior of microtubules, microtubules in cells are considerably less dynamic than previously appreciated. Microtubules in cells depend on accessory factors, such as the end binding (EB) proteins, to promote persistent assembly and disassembly factors, such as Kinesin-13s and Kinesin-8s, to antagonize assembly and promote turnover. Utilizing these regulatory factors, microtubules can effectively fill the cellular space available.

Microtubule-Depolymerizing Kinesins: Key Discoveries

In the mid-1980s, Ron Vale and Scott Brady independently reported the purification of a force-generating protein from the axoplasm of the squid giant axon that is capable of driving vesicle transport. This protein, termed conventional kinesin, is a homodimer that binds microtubules via one of two catalytic motor domains and uses energy derived from adenosine triphosphate (ATP) hydrolysis to translocate toward microtubule plus ends. Conventional kinesin, classified as a Kinesin-1, is one of 45 kinesin-like proteins encoded by the human genome. It was generally assumed that all kinesins would be transport motors that move along microtubules without influencing their dynamic properties.

In 1994, Endow and colleagues provided the first evidence that kinesins might also regulate the dynamic behavior of the tracks they translocate on. They observed that budding yeast Kar3 (Figure 1) is a slow minus-end-directed motor that has the capacity to depolymerize Paclitaxel-stabilized microtubules from minus ends. This finding was consistent with the observation that benomyl, a microtubule-destabilizing drug, could suppress the karyogamy defects exhibited by *kar3* mutants. In yeast, Kar3 controls microtubule plus-end dynamics during mating and is targeted to this location using the regulatory factor Cik1, a protein that heterodimerizes with Kar3. Kar3, a Kinesin-14, is evolutionarily conserved and its orthologs are characterized by having their catalytic domains at the C-terminus. Other well-studied Kinesin-14s such as *Drosophila* *ncd*, *Xenopus laevis* XCTK2, and human HSET also display minus-end-directed motility but thus far have not been reported to possess a microtubule destabilizing activity. Microtubule depolymerase activity may thus be restricted to fungal Kinesin-14s.

Members of the Kinesin-13 subfamily are the most potent of the microtubule disassembling kinesins. These motors are ancient, with orthologs present in divergent eukaryotes such as the intestinal parasite *Giardia intestinalis*. Kinesin-13s have an internally positioned motor domain (Figure 1) that is incapable of powering ATP-dependent motility. Kinesin-13s instead utilize ATP hydrolysis to catalyze the removal of tubulin subunits from both the plus and minus ends of microtubule protofilaments (Figure 2(a)). Humans express four Kinesin-13s: mitotic centromere-associated kinesin (MCAK; also called Kif2C), the first Kinesin-13 to be identified; Kif2A; Kif2B; and KIF24, a little studied motor thought to be the ancestral Kinesin-13.

Seminal studies of XKCM1, the MCAK/Kif2C ortholog in the African clawed frog *X. laevis*, in frog egg extracts were critical in demonstrating that Kinesin-13s are microtubule-destabilizing enzymes. Inactivation of XKCM1 led to the formation of long microtubules (Figure 5(a)), an effect that could be attributed to a reduction in the frequency at which microtubules transited from growth to shortening (catastrophe). Subsequent experiments with pure MCAK/Kif2C and Kif2A proteins revealed that Kinesin-13s could disassemble microtubules *in vitro* (Figure 3(a)), establishing a direct role for Kinesin-13s in the regulation of microtubule dynamics. Owing to their potency and biological importance, Kinesin-13s are the best understood and most intensively studied of the microtubule depolymerizing kinesins.

Kip3, a budding yeast Kinesin-8, is the most recent addition to the group of kinesins that possess a microtubule depolymerizing activity (Figure 1). Because yeast cells lacking *KIP3* contain long microtubules and because the motor domain of Kip3 is least divergent from the Kinesin-13s, it had long been postulated that members of the Kinesin-8 subfamily might be microtubule depolymerases. Recent studies with pure Kip3 motor have confirmed this and demonstrated that Kip3 is also a plus-end-directed motor. It is currently unclear whether the microtubule depolymerization activity of Kip3 has been retained throughout the eukaryotic kingdom. The heterodimeric Klp5/Klp6 Kinesin-8 from the evolutionarily distinct fission yeast *Schizosaccharomyces pombe* exhibits plus-end-directed motility but does not depolymerize microtubules *in vitro*. Similarly, Kif18A, one of three Kinesin-8s encoded by the human genome, does not appear to catalyze microtubule disassembly, but rather attenuates the dynamics of microtubule plus ends.

Biophysical Studies of Kip3 and Kinesin-13s

Considerable insight into Kinesin-13 and Kinesin-8 mechanisms has been obtained from biophysical and structural studies. The mysterious preference of MCAK/Kif2C for microtubule ends was explained by structural studies demonstrating that the high-affinity binding site for Kinesin-13 family members was a curved, rather than straight, protofilament. Curved protofilaments are most easily induced at the microtubule end. These motors stabilize the curved protofilament structure characteristic of depolymerizing microtubules. For unstabilized microtubules, such as those found in living cells, this has the effect of promoting catastrophes. Because Kinesin-13 family members can promote this activity only at the ends of microtubules, the motors must find the end of the microtubule without the benefit of directed motility. These motors can associate with the microtubule surface and diffuse in a directionally unbiased manner without any ATP hydrolysis until a microtubule end is encountered (Figure 3(c)). The rapidity with which the motor can associate with the microtubule lattice (on-rate) is the principal parameter governing the depolymerizing activity of the motor. This parameter is controlled by electrostatic interactions between the microtubule and positively charged regions outside of the motor domain. By changing the on-rate for the microtubule lattice, phosphorylation or posttranslational modifications of the microtubule itself can modulate the activity of these microtubule depolymerizers. Once associated with the microtubule lattice, the motor can use diffusive activity to encounter the microtubule end.

Once MCAK/Kif2C reaches the end of the microtubule, a high-affinity binding state to the curved protofilament end can be achieved (Figure 3(b)). Mutational analysis of switch II mutants of MCAK/Kif2C suggests that in the ATP-bound state, MCAK/Kif2C assumes a high-affinity state bound to the curved protofilament, breaks off one dimer as it reaches the ATP transition state, and then releases the dimer as hydrolysis is completed. Kinetic and biophysical studies have also predicted that one molecule of MCAK/Kif2C can remove approximately 20 tubulin dimers from GMP-CPP-stabilized microtubules before releasing from the microtubule. Whether

Figure 3 Biophysical properties of the Kinesin-13 MCAK/Kif2C. (a) MCAK/Kif2C depolymerizes microtubules from both ends. In the presence of ATP, GFP-MCAK/Kif2C targets the ends of a microtubule (red; here, stabilized with Paclitaxel) and catalyzes the removal of tubulin subunits, which is visualized as microtubule shortening. Time following exposure of the microtubule to GFP-MCAK/Kif2C is indicated in minutes. Scale = 1 μ m. (b) MCAK/Kif2C exhibits high affinity for microtubule ends. In the presence of the nonhydrolyzable ATP analog AMP-PNP, GFP-MCAK/Kif2C localizes to microtubule ends. Scale = 2 μ m. (c) MCAK/Kif2C diffuses along the microtubule lattice. In addition to direct microtubule end-binding, MCAK/Kif2C also targets microtubule ends by two-dimensional diffusion on the microtubule lattice. Shown are still images from a video depicting ATP-independent movement of GFP-MCAK/Kif2C along a microtubule. Time step is 200 ms. Scale = 2 μ m. (a) Image provided by Jeremy Cooper and Linda Wordeman. (b) Image provided by Ayana Moore and Linda Wordeman. (c) Image provided by Jeremy Cooper and Linda Wordeman.

MCAK/Kif2C would track with a disassembling dynamic microtubule once eliciting a catastrophe is not known, although a related *Drosophila* Kinesin-13 has been observed to track with the plus ends of disassembling microtubules. Finally, unlike the case with motile Kinesin-1s, it is still not known how or if the two heads of dimeric MCAK/Kif2C molecules are coordinated during tubulin removal.

The Kinesin-8 family members represent an interesting intersection between the microtubule depolymerizing kinesins described above and the well-studied motile kinesins of the Kinesin-1 family. Similar to Kinesin-1s, Kinesin-8s translocate to the plus end of the microtubule in an ATP-dependent

manner. The *S. cerevisiae* Kinesin-8, Kip3, can disassemble microtubules specifically from the plus end once a sufficient concentration of motors has accumulated there. Single-molecule studies reveal that Kinesin-8 motors exhibit strikingly higher processivity than the Kinesin-1s, taking many hundreds of steps before detaching from the microtubule. This interesting property suggests that Kinesin-8 motors are capable of translocating uninterrupted from one end of a cellular microtubule to the other without detaching. Furthermore, if the motors are capable of binding to the microtubule at any point along the lattice, the resulting motors will accumulate in a gradient extending from the plus end of the microtubule, a property that has been observed in mammalian Kinesin-8s. This has been proposed as a mechanism by which cells can set microtubule length or impart positional information along the length of the microtubule.

Upon reaching the plus end of the microtubule, the motor pauses until another motor approaches from behind. The arrival of another motor leads to the release of both the end-attached motor and its terminal tubulin dimer (Figure 2(b)) in a mechanism that is not understood but seems distinctly different from the Kinesin-13 mechanism of tubulin removal (Figure 2(a)). This behavior, in conjunction with observations from cellular and genetic studies, has led researchers to classify Kinesin-8s as modulators of microtubule-end dynamics similar to Kinesin-13s. While *in vitro* biophysical and kinetic studies utilizing dynamic microtubules have confirmed that Kinesin-13s promote microtubule catastrophes and lead to increased microtubule dynamics, similarly definitive studies using live microtubules remain ongoing for Kinesin-8s. However, preliminary studies in cellular systems suggest that Kinesin-8s regulate microtubule-end dynamics differently, possibly antagonistically, relative to Kinesin-13s.

Physiological Roles of Microtubule-Depolymerizing Kinesins

Microtubule-depolymerizing kinesins control microtubule polymerization dynamics to influence the architecture and functions of cellular microtubule-based assemblies. A key process in cell physiology that microtubule-depolymerizing kinesins participate in is cell division. During this period, the interphase microtubule array disassembles and re-organizes into the mitotic spindle, a highly dynamic apparatus that powers chromosome segregation. In part, this gross reorganization of the microtubule cytoskeleton is driven by a dramatic increase in microtubule dynamicity owing to a nearly five- to tenfold increase in the frequency of microtubule catastrophes. Elegant *in vitro* and *in vivo* studies have demonstrated that Kinesin-13s, particularly MCAK/Kif2C, are largely responsible for this change in microtubule dynamics. Without MCAK/Kif2C, spindle microtubules exhibit unbounded growth, an effect which impacts mitotic spindle assembly to varying degrees depending on the biological system. In embryonic *Xenopus* egg extracts, where the tubulin monomer pool is large, spindle formation is completely blocked whereas inhibition of MCAK/Kif2C in metazoan somatic cells leads to increases in spindle microtubule polymer, delayed centrosome separation, and delayed mitosis (Figures 5(a) and 5(b)).

In fungi, Kinesin-8 proteins also negatively regulate microtubule length, but the mechanism(s) and degree to which these proteins modify microtubule dynamics are unclear since most studies of these factors have been performed in live cells or on nonphysiological GMP-CPP microtubule substrates. Gene deletions of Kinesin-8s in both budding and fission yeasts (Kip3 and klp5/klp6, respectively) cause interphase microtubules to grow excessively long, and they are often observed to curl around cell tips. Catastrophe frequencies are reduced in cells lacking Kip3 and klp5/klp6 and, as discussed above, it is thought that these motors might actively catalyze microtubule shortening. In budding yeast, astral microtubule–cortex interactions specify the orientation and positioning of the mitotic spindle. Shortly after establishing a linkage, cortically attached microtubules depolymerize without dissociating from cortical attachment factors, causing nuclear translocation. Yeast cells lacking Kip3 misposition the mitotic spindle as a consequence of increased astral microtubule stability.

Kinesin-13s and Kinesin-8s also have critical functions at or near the plus ends of microtubules that interact with kinetochores, the chromosomal regions that constitute their primary interaction site with spindle microtubules. All Kinesin-13s and Kinesin-8s analyzed thus far exhibit prominent kinetochore localization (Figures 4(a)–4(c)). MCAK/Kif2C localizes to the inner kinetochore and centromeres (Figure 4(a)) and at this location polices kinetochore-microtubule attachments to ensure that chromosome segregation occurs without error. To segregate properly, chromosomes bi-orient or attach spindle microtubules such that each sister kinetochore is anchored to opposite spindle poles. MCAK/Kif2C depolymerizes flawed kinetochore-microtubule attachments, and, consistently, chromosomes are observed to mis-segregate in cells siRNA-depleted of MCAK/Kif2C (Figure 5(c)). How MCAK/Kif2C distinguishes between correct and improper attachments is not well understood. One model posits that MCAK/Kif2C continuously acts to depolymerize all kinetochore microtubules, and that

Figure 4 Localization of vertebrate microtubule-depolymerizing kinesins. (a) Localization of MCAK/Kif2C in a mitotic mammalian epithelial (PtK1) cell. The cell was fixed and immunostained for MCAK/Kif2C (green), kinetochores (red), and DNA (blue). (b) Localization of Kif2A in a PtK1 cell. The cell was fixed and immunostained for Kif2A (green), kinetochores (red), and DNA (blue). (c) Localization of Kif18A in mitotic human cervical carcinoma (HeLa) cell. The cell was fixed and immunostained for Kif18A (green) and kinetochores (red). Scale = 10 μm. Images provided by Ryoma Ohi.

Figure 5 MCAK/Kif2C uses its microtubule-depolymerizing activity to limit the length of mitotic spindle microtubules and prevent erroneous kinetochore-microtubule attachments. (a) The immunodepletion of MCAK/Kif2C from *Xenopus* egg extracts causes microtubules (orange) to grow abnormally long as a result of a reduction in microtubule catastrophe frequency. Normal spindles (inset) fail to form. Scale = 20 μm . (b) Removal of MCAK/Kif2C from HeLa cells by RNAi causes lengthening of astral microtubules (green). Scale = 10 μm . (c) MCAK/Kif2C prevents errors in kinetochore-microtubule attachment. In anaphase cells, siRNA-depleted of MCAK/Kif2C, mis-attached kinetochores (red) are observed to lag at the spindle equator (arrows). Scale = 10 μm . (a) Image provided by Ryoma Ohi. (b) Image provided by Kathleen Rankin and Linda Wordeman. (c) Image provided by Sarah Domnitz and Linda Wordeman.

increased stability of proper kinetochore-microtubule attachments protects them from detaching. However, MCAK/Kif2C is known to be regulated by the Aurora B kinase, a molecule with a well-established role in correcting kinetochore-microtubule attachment errors, and it is also expected that the ability of MCAK/Kif2C to depolymerize improper attachments is actively controlled by phosphorylation.

Kinesin-8 proteins localize to the plus ends of kinetochore microtubules (Figure 4(c)), where they play a key role in positioning chromosomes at the spindle equator. Careful analysis of chromosome movements in tissue culture cells siRNA-depleted of the Kinesin-8 motor Kif18A demonstrated that this motor acts to slow kinetochore movements and increase the frequency at which chromosomes switch their direction of movement. Paradoxically, this effect opposes the expected consequence of removing a kinetochore-associated microtubule depolymerase. It is conceivable that Kinesin-8 proteins act differently on chemically distinct microtubule substrates. The microtubule depolymerase activity of Kip3 has been studied most intensively on GMP-CPP microtubules that mimic the stable GTP cap, but how Kip3 acts on dynamic microtubules assembled from GTP is not known. Human Kif18A has been reported to attenuate the polymerization dynamics of GTP microtubules in a manner which reflects the effects of the motor on kinetochore oscillations. It is likely that ongoing work will clarify the mechanism(s) by which Kinesin-8 proteins govern kinetochore movements.

Kinesin-13s, particularly Kif2A (Klp10A in the fruit fly *Drosophila melanogaster*), also localize to spindle poles (Figure 4(b)) where they are thought to drive the poleward translocation of kinetochore microtubules in the mitotic and meiotic spindles of higher eukaryotic cells. In this process, termed poleward microtubule flux, kinetochore-attached microtubules treadmill polewards by depolymerizing at spindle poles where their minus ends are anchored. Depending on cell type, poleward flux of kinetochore microtubules can produce 20–100% of the forces necessary for sister chromatid segregation during anaphase. Although data suggesting that Kinesin-13s drive polewards flux in somatic tissue cells is strong, it is unclear if Kinesin-13s are important for poleward flux in the *Xenopus* extract spindle. In this system, the poleward translocation of most spindle microtubules is driven by Eg5, a homotetrameric Kinesin-5 motor that slides anti-parallel microtubules apart, and is largely unaffected by disrupting MCAK/Kif2C and Kif2A functions. Unlike somatic cells, however, kinetochore microtubules represent a small fraction of spindle microtubules and it is possible that changes in the flux rates of kinetochore microtubules are particularly difficult to measure.

MCAK/Kif2C limits the length of astral microtubules during cytokinesis, the process that individualizes two proto-daughter cells. Abnormally long microtubules, such as those produced in the absence of MCAK/Kif2C (Figure 5(b)), cause the anaphase spindle to oscillate along the spindle axis, putting the

cell at risk of incorrectly segregating its replicated genome. Such spindle rocking is caused by the formation and resorption of abnormally large blebs, which are balloon-like protrusions on the cell surface that form as a result of positive hydrostatic forces that rupture membrane-actin bonds. Long microtubules promote bleb inflation by invading them and delaying their myosin II-dependent resorption. If blebs are too large, strong cytoplasmic currents are generated that are capable of displacing the entire mitotic spindle.

The organismal function of Kif2A has been analyzed in mice through gene knockout technology. *Kif2A*^{-/-} mice survive to gestation, but die within 1 day after birth as a result of feeding abnormalities. This behavioral defect is thought to arise from widespread mistakes in neuronal wiring. Cortical neurons from homozygous-mutant animals exhibit migratory defects that are caused by the formation of long collateral branches, projections that form along the length of the primary axon. Collateral branch extension is thought to be driven by protrusive forces generated by microtubule plus ends that polymerize against the neurite edge. Excess Kif2A appears to suppress collateral branch formation by depolymerizing such microtubule plus ends.

Lastly, an ancient function of the Kinesin-13 motors is to regulate the length of flagella, slender whiplike microtubule-based projections that beat with regular rhythmicity. Flagellar length is dictated by a balance of microtubule-plus-end assembly and disassembly at the distal tip. Flagellar beating

powers the motility of sperm and many unicellular organisms, including protozoa of the Trypanosomatida family. *Leishmania* and *Trypanosoma*, two members of this family, have been shown to encode five Kinesin-13s. One, LmjKIN13-2, localizes to flagella tips where it uses its microtubule depolymerizing activity to actively shorten flagella. The single Kinesin-13 homolog in *G. intestinalis* also regulates flagellar length using ATP-dependent depolymerase activity. Whether Kinesin-13s regulate flagellar or ciliary length in animal cells is currently unknown.

Glossary

Axonal transport Axons transmit the signal from the cell body to the synaptic terminal. Because axons lack ribosomes, that is, the protein synthetic machinery, most of the proteins needed in the axon and synaptic terminal need to be synthesized at the cell body and transported. The transport in the direction from the cell body to synapse is called the 'anterograde transport'. Some molecules are transported in the opposite direction ('retrograde transport'). The proximal part of the dendrite contains ribosomes, although the number reduces at the distal region.

Cilia and flagella These contain microtubules in the '9 + 2' axonemal configuration (nine doublets and central pair of microtubules). The microtubules in the doublets slide along one another by the stroke of axonemal dynein, which bridges neighboring doublets.

Dynein Minus-end-directed microtubule motor. It forms a massive multisubunit complex composed of two to three heavy chains (~530 kDa), which have motor domains, and variable numbers of associated intermediate and light chains. There are two classes, axonemal and cytoplasmic.

Axonemal dyneins are attached to microtubule doublets in cilia and flagellar, and slide against microtubules producing the beating movement. Cytoplasmic dyneins are expressed in most eukaryotic cells and important in vesicle trafficking and cell division.

Microtubule A filament of 25 nm diameter assembled from α - and β -tubulin subunits (55 kDa). Microtubules, microfilaments (actin filaments), and intermediate filaments are the major cytoskeletal filaments. In addition to the structural role, microtubules serve as rails for the long-distance transport, and microfilaments serve as rails for the short-distance transport. Microtubules are also reorganized as mitotic spindle during mitosis, and play an important role in cell division.

Mitosis Replicated chromosomes are separated into two daughter cells, by a complex cytoskeletal machine called 'mitotic spindles'. The process proceeds as prophase, prometaphase, metaphase, anaphase, and telophase. Several different classes of KIFs and the cytoplasmic dynein participate in the complex movement of mitotic spindles.

Kinesin was first identified biochemically as a microtubule-dependent motor protein responsible for transport of membranous organelles in the axon. It is now recognized that microtubule-dependent motor proteins form a large gene family, kinesin superfamily proteins (KIFs). The human genome contains 45 KIF genes. KIFs have high homology at the so-called 'motor domain', which is a globular domain responsible for moving along microtubules by hydrolysis of adenosine triphosphate (ATP). Outside the motor domain, the sequence is unique to each member. The motors bind to the 'cargoes', the molecule to be transported, at this domain. KIFs transport many different types of cargoes including membranous organelles, protein complexes, and messenger RNAs (mRNAs). They play important roles in a wide variety of intracellular transport, such as transport from Golgi to plasma membrane pathways involved in exocytosis and endocytosis, axonal transport, transport in dendrites, and special transport called intra-flagellar transport. In addition, recent molecular genetic experiments have uncovered unexpected roles for KIFs in the regulation of such physiologic processes as higher brain function, tumour suppression, and developmental patterning. They also play important roles in mitosis. Functions and/or dysfunctions of KIF motors underlie some diseases. The molecular mechanisms by which different KIFs recognize and bind to specific cargoes, and how their binding is regulated, have been identified for some KIFs.

Introduction

The study of axonal transport provided the first clue that there is a microtubule-dependent motor protein that is not related to dynein. It has been known for quite some time that various membranous organelles and proteins are transported within axon, but the rails and motors were not known. Experimental evidence then suggested that long-distance transport within the axon is microtubule dependent. Quick-freeze deep-etch electron microscopy revealed that short cross-bridges were present between membranous organelles and microtubules, and these were likely to be a candidate for motor proteins (Figure 1). In the mid-1980s, 'conventional kinesin (KIF5)' was first isolated biochemically as motor protein responsible for the transport of membranous organelles in the direction of cell body to synapse. Conventional kinesin has a rod-like structure composed of two globular heads (10 nm in diameter), a stalk, and a fanlike end, with a total length of 80 nm (Figure 2). The globular heads bind to microtubules and have an adenosine triphosphate (ATP)-binding sequence and a microtubule-binding sequence. A systematic molecular biological search of kinesin superfamily genes coding for proteins containing similar ATP-binding and microtubule-binding sequences led to the discovery of a group of motors, which is now called kinesin superfamily proteins, KIFs (Figures 2 and 3). Human genome contains 45 KIF genes. KIFs in the human

and mouse genomes are presented in a phylogenetic tree along with those in *Saccharomyces cerevisiae*, *Drosophila melanogaster*, and *Caenorhabditis elegans* in **Figure 4**. KIFs identified in mouse are named as KIF1–KIF26, and KIFC1–KIFC3. KIFs identified in other species have various names. **Figure 4** also shows classes based mostly on murine and human KIFs, N-1 to N-11, M, C-1, and C-2. However, recently, a group of researchers in the field defined a new standardized nomenclature for classification of kinesins, based on 14 large families, Kinesin-1 to -14, to

Figure 1 Quick-freeze deep-etch electron micrographs showing short cross-bridges between membranous organelles and microtubules that are structural candidates for KIFs. Scale = 50 nm. facilitate understanding of evolutionary relatedness of genes identified in different names in various phylogenies (**Table 1**). To minimize confusion, it was decided that the names of individual motors will remain unchanged. The relationships of newly standardized family names and former classes are shown in **Table 1**. For clarity, the nomenclature in the mouse will be used as much as possible in this article. However, for some KIFs other names will be used.

Although all members of KIFs share a highly homologous domain having ~350 amino acids containing a site for ATP binding and one for microtubule binding, they are quite divergent outside the motor domain. This seems to allow the binding of KIF to various cargoes, including membrane-enclosed vesicles, macromolecular complexes, and messenger RNAs (mRNAs), and they play important roles in various transport processes including axonal transport, transport in dendrite, intracellular vesicular trafficking such as pathways involved in endocytosis and exocytosis, and special transport called ‘intraflagellar transport’ (**Table 1**). For most of the KIFs, the motor domain resides at the N-terminal portion of the molecule (N-kinesin), but the motor domain could be in the C-terminal (C-kinesin) or the middle of the molecule (M-kinesin) (**Figure 3**). The range of the size of a typical KIF molecule is from 600 to 1800 amino acids (**Figure 3**). Different KIFs take various forms (**Figure 2**). Some are homodimer with or without associated light chains; some are monomeric; some are heterodimer with associated protein; and some are homotetramer forming bipolar minifilaments. Some KIFs bind their cargo directly, and some do so via light chains or associated proteins, discussed individually in this article.

Microtubule has a polarity. It has a fast-growing plus-end, and opposite minus-end. In the nerve cell axons, the microtubules are unipolar, the plus-end pointing to the direction of synapse (**Figure 5(a)**). However, in dendrites microtubules have mixed polarity in proximal region, while they are oriented like in axon in the distal region. In interphase cells, microtubules are in a radial array with the minus-end pointing

the cell center, and the plus-end pointing the cell periphery (Figure 5(b)). The direction of transport and velocity of each motor can be assessed in the so-called ‘*in vitro* motility assay’. Most of the KIFs are plus-end-directed motors, including conventional KIFs. Some KIFs are minus-end-directed motor, but the minus-end-directed transport is also carried out by cytoplasmic dynein (Figures 5(a) and 5(b)). In general, N-kinesin and M-kinesin are plus-end directed, and C-kinesin is minus-end directed. The typical velocity is within the range of $0.1\text{--}1.5\ \mu\text{m s}^{-1}$. In comparison, microtubule minus-end directed motors dyneins, which are one of the fastest motors, have a velocity of $\sim 14\ \mu\text{m s}^{-1}$. The direction obtained from *in vitro* assay generally agrees with that predicted from *in vivo* study. However, one may need to be somewhat cautious in interpreting the velocity of *in vitro* assay, because, for some KIFs, the condition of *in vitro* motility assay may not be optimal.

The characteristics of some KIFs, whose functions are relatively well characterized, are summarized in Table 1. Cargoes and physiological roles of some well-characterized KIF are described next.

N-Kinesin

N-kinesin holds by far the largest number of members and it consists of 12 classes, Kinesin-1 through Kinesin-12. Some classes have more than one family.

Kinesin-1 (N-1 Kinesins)

The KIF 5 family

Conventional kinesin corresponds to KIF5. KIF5 forms tetramers consisting of two kinesin heavy chains (120 kDa) and two light chains (64 kDa). Light chains are unrelated in sequence to kinesin. They are a rod-like structure composed of two globular heads, a stalk, and a fanlike end, in which the light chains reside (Figure 2). KIF5 is a plus-end-directed motor with a velocity of $\sim 0.5\ \mu\text{m s}^{-1}$. KIF5 is relatively abundantly expressed in both nervous tissue and other tissues, and transports an amazingly wide variety of cargoes including vesicles containing amyloid precursor protein (APP), GAP43, ApoER2, the receptor for the Reelin ligand, or the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptor GluR2,

Figure 4 Phylogenetic analysis of all KIFs expressed in mouse/human, *D. melanogaster*, *C. elegans*, and *S. cerevisiae*. Amino acid sequences were aligned using maximum parsimony. Reproduced with permission from Miki H, Setou M, Kaneshiro K, and Hirokawa N (2001) All kinesin superfamily protein, KIF, genes in mouse and human. *Proceedings of the National Academy of Sciences of the United States of America* 98: 7004–7011, © 2001 National Academy of Sciences, USA.

mitochondria, and lysosomes (Figures 5(a) and 5(b)). KIF5 could also convey mRNA complexes, tubulin oligomers and intermediate filament proteins. Recently the direct interactions between KIF5 and some of the cargoes have been shown

(Figure 6). KIF5 may interact with certain cargoes via light chains, and yet with other cargoes via heavy chain. Moreover, whether KIF5 interacts via light chains or heavy chains may determine the destination. Glutamate receptor interacting

protein 1 (GRIP1) binds to the tail domain of kinesin heavy chain and transports AMPA-type glutamate receptor (GluR2)-containing vesicles to dendrites, while JIP1,2 steers ApoER2-containing vesicles to axons through its interaction with light chains (Figure 6).

Kinesin-3 (N-3 Kinesins)

The *Unc104/KIF1* family

KIF1A and KIF1B β are plus-end-directed motors of ~190 kDa, which are relatively abundantly expressed in the axon and

Figure 6 Scheme of how KIFs recognize and bind cargoes. Reproduced from Hirokawa N and Takemura R (2003) Kinesin superfamily proteins. In: Schliwa M (ed.) *Molecular Motors*, pp. 79–109. Weinheim: Wiley-VCH, with permission.

transport precursors of synaptic vesicles. They are monomeric motors, which is rather unique compared to other KIFs (Figure 2). They are also one of the fastest KIFs ($\sim 1.5 \mu\text{m s}^{-1}$) (Table 1). Unc104 is a homolog of mouse KIF1A. The knockout mice of KIF1A and KIF1B β show aberrant neuronal functions due to the defect in the transport of precursors of synaptic vesicles. Further study showed that patients with Charcot–Marie–Tooth disease type 2A carry a loss-of-function mutation in the motor domain of the *kif1b* gene. This was the first clear indication that impaired transport due to dysfunction of KIF motors underlies the cause of neurodegenerative disease. KIF1B α is a plus-end-directed motor ($\sim 0.5 \mu\text{m s}^{-1}$) expressed ubiquitously and transports mitochondria.

The KIF13 family

KIF13A is a plus-end-directed motor with the velocity of $0.1\text{--}0.3 \mu\text{m s}^{-1}$ and transports vesicles containing the mannose-6-phosphate receptor from the *trans*-Golgi network to the plasma membrane (Figure 5(b)). The interaction of KIF13A with the vesicle is mediated via direct interaction between KIF13A tail and β -1-adaptin, a subunit of the AP-1 adaptor complex (Figure 6).

Kinesin-2 (N-4 Kinesins)

The KIF3 family

The KIF3 forms a heterotrimeric complex, in which a heterodimer of KIF3A (80 kDa) and KIF3B (~ 95 kDa) interact at its

tail domain with a nonmotor protein, kinesin superfamily-associated protein 3 (KAP3, ~ 100 kDa) (Figure 2). The KIF3 complex is plus-end directed with a velocity of $\sim 0.3 \mu\text{m s}^{-1}$. KIF3 is relatively abundantly expressed in the axon and other tissues, and functions in axonal transport, intracellular transport, and in the intraflagellar transport (IFT). In the axon, the complex transports vesicles that carry fodrin and choline acetyltransferase, a soluble protein. In melanophore, it disperses pigment organelles called ‘melanosomes’. In cilia and flagella, the KIF3 complex transports macromolecular protein complexes, called ‘IFT particles’, from the bottom to the distal tip, which is important in the formation and maintenance of cilia and flagella. In retinal photoreceptor cells, the KIF3 complex is localized in the connecting cilium, which is located between the outer and inner segment. KIF3 complex participates in the transport of opsin from the inner to the outer segment at the connecting cilium; the impairment of this transport process could be one of the causes of retinitis pigmentosa.

An interesting aspect of KIF3 is its involvement in development. First, by its involvement in cilium formation, it plays a significant role in the determination of the left–right axis in early mouse development. During mouse development, there is a monocilium at the nodal cell that rotates to produce unidirectional leftward flow of extraembryonic fluid. This nodal flow could generate concentration gradients of putative secreted morphogen, which could switch on a gene cascade leading to left–right asymmetry. In *kif3A* (–/–) or *kif3B* (–/–) mouse, nodal cilia cannot be formed, nodal flow is absent, and the left–right axis formation is fundamentally impaired.

Second, KIF3 is involved in post-Golgi transport of N-cadherin/ β -catenin, which plays a role in adhesion of neuronal progenitor cells. In mice deficient in expression of KAP3 at post-midgestation stage, the subcellular localization of N-cadherin/ β -catenin was disrupted. β -Catenin tended to be localized in the nucleus to work as a transcriptional factor to enhance cell proliferation. The tumor-like abnormal hypertrophy of the cerebral cortex was observed suggesting that KIF3 may play roles in tumor suppression by transporting N-cadherin/ β -catenin from the Golgi to the plasma membrane.

The KIF17 family

KIF17 is localized to the dendrites and transports vesicles containing N-methyl-D-aspartate (NMDA)-type glutamate receptor 2B toward the microtubule plus end to the postsynaptic site, where the receptor plays an important role in synaptic plasticity (Figure 5(a)). The large protein complex containing mLin-10, mLin-2, mLin-7, and NR2B mediates the attachment of KIF17 to the vesicle (Figure 6). The tail domain of KIF17 interacts directly with the PDZ domain of mLin-10. Transgenic mice overexpressing KIF17 increase synthesis of KIF17 and NR2B and enhance spatial and working memories.

Other N-Kinesins

For the rest of the N-kinesin members, the physiological function has been elucidated to varying degrees. The members of Kinesin-5 (N-2 kinesins), *Homo sapiens* Eg5 or *Caenorhabditis elegans* BimC, form bipolar tetramer and participate in mitosis. They localize at the midzone of interpolar microtubules, where microtubules run in antiparallel orientation. They cross-link microtubules and allow their sliding against each other. Kinesin-6 (N-6 kinesins) is involved in both mitosis and vesicle transport. Kinesin-7 (N-7 kinesins) and Kinesin-8 (N-8 kinesins) are also involved primarily in mitosis.

KIFs are also involved in signaling transductions. The member of Kinesin-4 (N-5 kinesins), KIF4, regulates neuronal survival by binding to poly (ADP-ribose) polymerase-1 (PARP-1), a nuclear enzyme known to maintain cell homeostasis. The C-terminal domain of KIF4 is a module that suppresses the activity of PARP-1. When neurons are stimulated, KIF4 dissociates from PARP-1, resulting in upregulation of PARP-1 activity, which supports neuronal survival. Thus, KIF4 plays a significant role during brain development as a key molecule to control activity-dependent neuronal survival. The member of Kinesin-11 (N-11 kinesins), KIF26A, lacks ATPase activity, but suppresses glial cell-derived neurotrophic factor (GDNF) signaling pathway by binding to Grb2, an essential component of GDNF/Akt/ERK signaling. GDNF signaling regulates development of enteric nervous system. Mice with a homozygous deletion of KIF26A develop a megacolon with abnormal enteric nerve system. Kinesin-2 also includes the Costal 2, which is a part of the hedgehog-signaling cascade.

M-Kinesins

Kinesin-13 (M-Kinesins)

M-kinesins have a motor domain at the center of the molecule. There is only one family in this group, namely the KIF2 family,

which is composed of *kif2a*, *kif2b*, and *kif2c* genes. KIF2 family has functional roles in vesicle transport and mitosis. However, a unique feature of M-kinesins is regulation of microtubule dynamics, namely a microtubule-depolymerizing activity, which has been shown by X-ray crystallography to be due to the position of the motor domain within a molecule. *Xenopus* XKCM1 depolymerizes microtubules at the kinetochore and promotes chromosome segregation. In the brain of *kif2a* (–/–) mouse, neurons form abnormally elongated collateral branches. In contrast, in the wild-type mouse, shorter collaterals are formed. It was shown that in case of wild-type mouse, KIF2A suppresses microtubule polymerization at the tips of growth cones of developing neurons, which results in controlling the extension of collateral branches. This indicates that KIFs could play roles in brain wiring.

C-Kinesins

Kinesin-14A (C-1 Kinesins)

The KIFC1 family

Drosophila Ncd cross-links and slides antiparallel spindle microtubules in relation to another, pulling them apart, opposing the effect of bipolar plus-end-directed motors.

Kinesin-14B (C-2 Kinesins)

The KIFC2/KIFC3 family

KIFC2 transports multivesicular body-like membranous organelles in dendrites (Figure 5(a)). It has not been rigorously demonstrated, but it is presumed that KIFC2 acts as a minus-end-directed motor.

KIFC3 is a minus-end-directed microtubule motor protein that exists in kidney epithelial cells and other types of cells. In epithelial cells, microtubule organization is different from that in other types of cell; microtubule minus ends run toward the apical surfaces of the cell. KIFC3 accumulates on the apical surface of epithelial cells and transports vesicles associated with annexin XIIIb, a previously characterized membrane protein for apically transported vesicles.

Perspectives

Cargoes of KIFs: Specificity and Redundancy

As mentioned earlier, KIFs convey various types of cargoes. In some cases, a single KIF transports several distinct cargoes. How the same KIF can transport different cargoes is an interesting and important question that needs to be addressed.

At the same time, KIFs sometimes redundantly convey similar cargoes. KIF1B α transports mitochondria, while mitochondria have another redundant motor KIF5. KIF1A's cargo is a synaptic vesicle precursor, whereas KIF1B β also conveys synaptic vesicle precursors. Another example is lysosomes that have at least two microtubule plus-end-directed motors, KIF5 and KIF2A β . This redundancy could be a cause of subtle phenotypes of knockout mice in which some *kif* genes have been knocked out.

Recognition and Binding to Cargoes

To address the question of how specificity and redundancy are controlled, it is important to understand how KIFs recognize

and bind to their own cargoes. As discussed earlier, some of the interactions of KIFs and cargoes are beginning to be uncovered.

In terms of how KIFs recognize and bind cargoes, several forms can be categorized (Figure 6):

1. *KIF tail – scaffolding protein(s) or adaptor protein(s) – membrane protein.* This is applicable to KIF17-mLin-10-mLin-2-mLin-7-NR2B, KIF13A- β 1adaptin-AP-1adaptor complex-M6PR, KLC-JIP1/JIP2-ApoER2, the reelin receptor, and KIF5 (KHC)-GRIP1-GluR2.
2. *KIF tail – membrane protein.* Kinesin was reported to bind directly to membrane proteins through its interaction with KLC. Sunday Driver (also called JSAP1 and JIP3) and APP were proposed to be membrane proteins that bind directly to kinesin through KLC, while it needs to be studied further if Sunday Driver (JSAP1 and JIP3) is indeed a membrane protein.

It is only now being understood how KIFs recognize and bind to their specific cargoes, but thus far what was only known was that rather complex mechanisms are involved in these events. This may be related to how the association and dissociation between KIFs and cargoes are regulated. Another question is how KIFs recognize and bind to protein complexes such as tubulin and intermediate filament proteins, chromosomes, and mRNAs. These are obviously significant questions that need to be answered in the near future.

Regulation of Binding to Cargoes

For efficient cell function and morphogenesis, cargoes need to be delivered to their destinations by specific KIFs and unloaded from these KIFs at the appropriate time and place. Recent studies have started to reveal the regulatory mechanisms of the spatiotemporal delivery of cargoes. In some cases, the phosphorylation of KIFs seems to regulate their binding to cargoes. For example, phosphorylation of KIF17 by the Ca^{2+} /calmodulin-dependent protein kinase CaMKII disrupts the interaction of KIF17 and its interacting partner mLin-10. In other cases, members of Rab family of small guanosine triphosphatases seem to be involved in the regulation. For example, KIF1A and KIF1B β transport Rab3-carrying synaptic vesicle precursors through the adapter protein, mitogen-activated protein, kinase-activating death domain (MADD; also known as DENN/MADD). DENN/MADD recognizes the guanosine triphosphate-bound form of Rab3 on vesicles, but not the guanosine diphosphate-bound form.

How to Determine Directions of Transport

Another intriguing question is how a cell regulates direction of transports, for example, axon versus dendrites. In the case of KIF5, whether KIF5 binds to cargoes via heavy chain or light chain seems to determine the direction of transport, and JIP1.2

and GRIP1 are functioning as drivers (Figure 6). There are motors that transport cargoes mainly to dendrites. KIF17 conveys NMDA receptors mainly to dendrites and KIFC2 transports new multivesicular body-like organelles to dendrites. KIF21B was also proposed to be a motor for dendritic transport. How differential transports are performed is clearly the fundamental question that needs to be solved in the near future. The mechanism is probably not simple and could involve several distinct events.

Thus, cells use interestingly many KIFs and very precisely control the direction and velocity of transport of various distinct cargoes that are fundamental in cellular basic functions. This field is obviously very important and rapidly advancing. Further studies need to be carried out to understand the entire mechanism of intracellular transport.

Glossary

Commitment to catalysis The rate constant for the conversion of ES to EP divided by the rate constant for the return of ES to E + S.

Intrinsic isotope effect The isotope effect when the bond cleavage or bond reorganization event completely limits the reaction rate.

Nuclear tunneling A process whereby an atomic nucleus, because of its wave-mechanical nature, is able to penetrate rather than surmount an energy barrier.

Zero-point energy The potential energy present in a bond at 0 K.

Isotopes are atoms that have identical numbers of protons and different numbers of neutrons in their nuclei. Because the electron distributions of molecules composed of isotopic atoms are identical, they exhibit identical chemical reactivity patterns. In reactions where bonds to isotopically labeled atoms are made and broken, rates are affected in proportion to the masses of the reacting bonds. Ratios of rates for such reactions are termed kinetic isotope effects (KIEs). KIEs are largest when bonds are made and broken at the site of isotopic substitution (a primary effect) but also are seen when significant reorganization occurs peripheral to a site that undergoes a change in bonding (a secondary effect). Both types of KIEs reflect the nature of the energy barrier to a fundamental chemical reaction. Primary hydrogen KIEs typically vary between two and eight, while the largest secondary hydrogen effects are <1.5. Thus, secondary KIEs often require the use of competitive methods and highly sensitive techniques to analyze product distributions, whereas primary KIEs can be detected using noncompetitive and less accurate techniques.

Physical Origin of KIEs

Primary KIEs have mostly been determined for reactions of carbon, nitrogen, and oxygen atoms bonded to the isotopes of hydrogen: protium (^1H), deuterium (^2H), and tritium (^3H). Such processes, which include proton, hydrogen atom, and hydride transfer, have been studied extensively in enzymes, solution phase and to a lesser extent in the gas phase. The observation of a primary KIE is conventionally understood using a semiclassical model. The model is semiclassical because it takes into account the quantization of energy in chemical bonds but does not explicitly deal with the dual wave/particle nature of the constituent atoms.

Chemical Bonds as Harmonic Oscillators

A chemical bond can be described as two massive bodies attached to a spring. The particles experience a restoring force that is proportional to their displacement (x) by the

force constant (F). Hooke's law (eqn [1]) relates the frequency of motion (ν) to the reduced mass (μ) of the atoms undergoing oscillation (eqn [2]) and the force constant characteristic of the bond. Force constants are the same for isotopic bonds and changes in vibration frequency result from changes in μ . The largest perturbation in ν is caused by changes in μ upon substituting deuterium or tritium for protium:

$$\nu = \frac{1}{2\pi} \sqrt{\frac{F}{\mu}} \quad [1]$$

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \quad [2]$$

The oscillations of atoms from their equilibrium positions can be approximated by a harmonic function. The energy of a bound particle ($h\nu$) is defined by the harmonic-oscillator approximation according to eqn [3], where h is Planck's constant ($h = 6.626 \times 10^{-34} \text{ J s}$) and vibrational energy levels are designated n_{vib} . The zero-point energy ($n_{\text{vib}} = 0$) is the lowest vibrational energy level of a harmonic oscillator. These zero-point energies dominate the origin of KIEs within a semiclassical picture:

$$E_{\text{vib}} = (n_{\text{vib}} + 1/2)h\nu, \quad n_{\text{vib}} = 0, 1, 2, \dots \quad [3]$$

Wave/Particle Dualism

Particles also have wavelengths, with this property dependent on the mass (m) and velocity (v) of the particle. At constant energy, the wavelengths of unbound particles follow from the de Broglie equation (eqn [4]):

$$\lambda = h/mv \quad [4]$$

Defining the unbound particle's kinetic energy as $E_k = (\frac{1}{2}mv^2)$ allows de Broglie wavelengths to be calculated (Table 1). The arbitrarily assigned kinetic energies are characteristic of barrier heights encountered in many (C, N, or O)–H cleavage reactions. According to eqn [3], $E_k \sim 4 \text{ kcal mol}^{-1}$ approximates the potential energy present in (C, N or O)–H bonds ($\nu = 3000 \text{ cm}^{-1}$) at 0 K. When the electron is compared to the proton and then to an oxygen nucleus, there is an extremely

Table 1 de Broglie wavelengths as a function of mass and kinetic energy

Particle	e^-	^1H	^2H	^3H	^{12}C	^{16}O	^{80}Br
Mass ($\times 10^{27}$ kg)	0.000 911 0	1.661	3.321	4.982	19.93	26.57	132.8
λ (Å), $E_k = 4$ kcal mol $^{-1}$	29.40	0.69	0.49	0.40	0.20	0.17	0.077
λ (Å), $E_k = 10$ kcal mol $^{-1}$	18.60	0.44	0.31	0.25	0.13	0.11	0.049

large variation in the quantum wavelengths ranging from 29.40 Å to 0.69 Å to 0.17 Å, respectively. The values indicate that the de Broglie wavelengths for the electron and hydrogen are comparable to the distances traversed by these particles in chemical reactions, consistent with experimental findings that indicate a dominance of their reactivity by quantum mechanical behavior.

KIEs as Mechanistic Probes

KIE measurements are routinely used for the elucidation of reaction mechanisms. The reaction coordinate represents the three-dimensional motion of all nuclei along the lowest-energy path that interconverts reactants and products. The reaction coordinate may represent the displacement of atoms within a chemical bond and/or the reorientation of surrounding solvent molecules. Regardless of the nature of the reaction coordinate, isotope substitution does not change the electronic potential energy surface for the reaction. Reaction rates vary with isotopic perturbation due to changes in vibrations that directly or indirectly couple to the reaction coordinate and by a decrease in wavelength for heavier atoms.

Activation Energy and Transition State Theory

In the year 1889, Svante Arrhenius documented the observation that chemical reaction rates vary as a function of temperature, predating the discovery of the first isotope, deuterium, in 1932. The Arrhenius equation (eqn [5]) expresses a rate constant (k) as an exponential function of thermal activation energy (E_{act}). Together, the temperature (T) and the gas constant (R) define the population of states that, as the result of molecular collisions, have sufficient E_{act} for reaction. The A term, originally referred to as a frequency factor, reflects the rate at which an activated complex (one possessing E_{act}) decomposes to product:

$$k = A \exp(-E_{\text{act}}/RT) \quad [5]$$

The transition-state theory (TST) developed separately by Eyring and by Evans and Polanyi (c. 1935) is the preeminent model for interpretation of energy barriers to chemical reactions. TST gives the rate of reaction in terms of the molecular-level properties of an activated complex or transition state. Unlike the phenomenological Arrhenius equation, TST defines the energy difference between reactant and transition state using translational, rotational, vibrational, and electronic (gas phase) partition functions. The reaction coordinate is treated classically and separated from all of the other classical and

Figure 1 Reaction coordinates for $\text{H}^\bullet$ abstraction from methane by $\text{Cl}^\bullet$ depicting the transition state as the intersection of potential energy surfaces for stretching C–H and H–Cl bonds.

quantum modes. The transition state occupies the dividing surface separating reactants from products and contains all degrees of freedom orthogonal to the reaction coordinate. The fundamental assumption of classical TST is that reactants do not re-cross the dividing surface and products are formed with the frequency of a bond vibration or solvent fluctuation once the transition-state configuration is attained. This assumption is relaxed in the semi-classical expression given by eqn [6], where the rate constant is expressed in terms of an equilibrium constant for the formation of the transition state from the reactant state $\{K^\ddagger = \exp(-\Delta G^\ddagger/RT)\}$ and a frequency factor ($\kappa(k_B T/h)$). In the pre-exponential term, k_B is Boltzmann's constant and κ appears as a correction factor for the nonunit probability that products will form each time the reactants attain the energy of the transition state:

$$k = \kappa \frac{k_B T}{h} \exp(-\Delta G^\ddagger/RT) \quad [6]$$

Figure 1 shows a curve-crossing diagram for a molecule of methane reacting with atomic chlorine. The transition state is denoted by 'double dagger' and represents a configuration for H atom transfer where the C–H bond is stretched and there is an attractive force between the Cl and H atoms. Thus, the reaction coordinate is the stretching of the bond. This situation is depicted further in Figure 2, where reaction occurs when an energy barrier is surmounted that converts the stretching

Figure 2 Energy diagram representing the origin of KIE on cleaving a C-H or C-L bond ($H = {}^1\text{H}$, $L = {}^2\text{H}$ or ${}^3\text{H}$). In this figure, a stretching mode in the reactant has been converted to a translational mode in the transition state.

motion of a C-H (or C-L, where $L = {}^2\text{H}$ or ${}^3\text{H}$) bond to a translational degree of freedom.

Although the nature of the reaction coordinate is not specified in the original derivation of TST, diagrams akin to **Figure 2** have been used extensively for pedagogical reasons. The transition state is not an intermediate and has no detectable lifetime. The curvature of the reaction coordinate in the transition state region is defined by an imaginary frequency for the C- ${}^1\text{H}$ or C-L vibration that is lost. Clearly, this formulation of a bond-stretching reaction coordinate is an oversimplification when frequencies are high. When $h\nu \gg k_B T$, the reacting bonds are essentially frozen and should not contribute much to the activation energy for reaction.

Isotope Effects from Zero-Point Energies

According to the Born–Oppenheimer approximation, the mass disparity between an electron and a nucleus allows the timescale for electronic motion to be separated from the much slower nuclear motion. It follows that reduced mass differences cause the zero-point energies to follow the trend $\text{C}-{}^1\text{H} > \text{C}-{}^2\text{H} > \text{C}-{}^3\text{H}$, as shown in **Figure 2**. Neglecting differences for reactions of isotopic molecules due to their quantum wavelengths, KIEs can be calculated from activation energies.

In the simplest case, the reaction coordinate involves conversion of a ground-state stretch to a translation and, hence, neglects isotopic zero-point energies in the transition state. The differences in the zero-point levels of the reactant state give the upper limit to the primary KIE through **eqn [7]**, where the subscript L designates either of the heavier isotopes of hydrogen. From the stretching frequencies of C- ${}^1\text{H}$

($\nu = 3000\text{ cm}^{-1}$), C- ${}^2\text{H}$ ($\nu = 2200\text{ cm}^{-1}$), and C- ${}^3\text{H}$ bonds ($\nu = 1800\text{ cm}^{-1}$), KIEs of 7 and 18 are estimated for $k_{1\text{H}}/k_{2\text{H}}$ and $k_{1\text{H}}/k_{3\text{H}}$ at 298 K, respectively:

$$\frac{k_{1\text{H}}}{k_L} = \exp\left[\frac{h(\nu_H) - h(\nu_L)}{2RT}\right] \quad [7]$$

The Melander–Westheimer principle (c. 1960) models the parabolic variation of primary KIEs in terms of a linear transition state for hydrogen transfer (cf. **Figure 1**). The symmetry of the transition state depends on the overall reaction thermodynamics. Asymmetry increases as the transition state becomes more reactant like (or earlier along the reaction coordinate) for exothermic reactions or more product like (later) in an endothermic reaction. For real molecules that contain multiple degrees of vibrational freedom, compensating vibrations that are isotopically sensitive will reduce the size of the isotope effect from its peak at a symmetric transition state.

Deviations from Predicted Values

In general, observed primary KIEs are less than the upper limit set by **eqn [7]**. Observations of values larger than those predicted by **eqn [7]** have been observed and tentatively attributed to an insufficient description of the reaction coordinate. For instance, KIEs may appear inflated when isotope labels in secondary positions contribute to differences in E_{act} . As discussed in the monograph by Melander and Saunders, KIEs may be up to threefold larger because of restricted transition-state geometries wherein bending vibrations present in the reactant state have been lost.

In contrast to effects ascribable to the ratio of reactant and transition-state partition functions, non-Boltzmann effects such as nuclear tunneling may also give rise to large isotope effects. Tunneling has historically been treated as a correction, with the dominant contribution to the rate constant viewed as the activation energy associated with distortion of the reacting bond. However, there has been a resurgence of attention to quantum phenomena in the chemical and biochemical literature. New models for proton, hydrogen atom, and hydride transfer reactions are being developed which presuppose tunneling mechanisms and formulate reaction coordinates in terms of the collective low-frequency motions of heavy atoms and the surrounding solvent molecules or protein. It is important to realize that a wide range of KIEs with values both larger and smaller than those predicted by **eqn [7]** are consistent with mechanisms of tunneling, where reactants do not need to have the activation energy required to reach the transition state and reaction may occur by passing through rather than over the potential energy barrier.

KIEs as Mechanistic Probes during Enzyme Catalysis

By virtue of being a catalyst, an enzyme accelerates a chemical reaction without changing the overall thermodynamics. The term catalysis frequently refers to a multistep reaction such as the oxidation of glucose to gluconolactone and reduction of O_2 to H_2O_2 as it occurs in the glucose oxidase reaction (**eqn**

[8]). Additionally, the term catalysis may refer specifically to a single chemical step that is accelerated by lowering or circumventing an energy barrier.

To understand the role of an enzyme during a catalytic transformation, the substrate-binding step and chemical step, where reactants are converted to products, must be analyzed separately. Assessment of barrier-lowering effects requires comparison of the enzymic reaction to a solution-phase reaction, both referenced to some standard state:

Experimental Considerations

Primary, secondary, and solvent KIEs can be used to elucidate the extent to which a change in bonding occurs in or before the rate-determining step. Primary effects are invariably normal, that is, the light isotope reacts faster than the heavy one. Secondary effects may show inverse behavior when the reaction is characterized by an increase in bonding and the difference in zero-point energies in the transition state is greater than in the reactant state. Primary effects are typically measured for reactions where protium is exchanged for deuterium and/or tritium, but isotope labeling of the heavy atoms may also give rise to measurable effects.

The largest effects are predicted upon isotopic substitution of protium because of the sizable perturbation to the zero-point energy levels as discussed earlier. Because reactions involving the transfer of protium and its isotopes give rise to the largest effects, experiments performed noncompetitively, using the pure labeled substrates in separate reaction solutions, require high isotopic enrichment in addition to chemical purity. Isotopic purity becomes crucial when KIEs are >10 and only 5% contamination of the heavy isotope by the light isotope will cause an apparent deflation of the KIE by a factor of >1.4 .

Secondary KIEs are typically much smaller and are, therefore, most often measured by competitive techniques. While isotope purity is not required, sensitive methods such as scintillation counting of radiolabeled products or mass-spectrometric analysis of chemically labeled products are necessary. Intra-molecular measurements can be more informative than inter-molecular measurements, as spurious isotope discrimination due to differential binding effects is absent. However, the determination of intra-molecular primary isotope effects on enzymatic reactions is, most generally, precluded by the inherent stereoselectivity imparted by the protein.

An Example from Glucose Oxidase Catalysis

Glucose oxidase mediates the oxidation of glucose and other simple six-carbon sugars. Enzymes isolated from fungi have been the subjects of extensive mechanistic studies due in large part to their robustness under a variety of temperature and pH

Figure 3 The isoalloxazine rings of oxidized (FAD) and reduced (FADH⁻) flavin adenine dinucleotide.

conditions. The active enzyme is a homodimer that contains one noncovalently bound flavin adenine dinucleotide cofactor (Figure 3) per subunit. The flavin adenine dinucleotide (FAD) is reduced by simple sugars in the reductive half-reaction to produce FADH⁻, which is oxidized by molecular O₂ in the oxidative half-reaction. A ping-pong-type kinetic mechanism has been demonstrated for glucose oxidase wherein the first substrate binds, gets converted to product, and is then released prior to the reaction of the second substrate (Figure 4).

The mechanisms advanced for the reactions of sugars with glucose oxidase involve cleavage of the anomeric C–H in the rate-determining step (eqn [8]). The main evidence is the significant primary KIEs observed upon isotope labeling of this position in glucose and in the alternative, slower-reacting substrate 2-deoxyglucose. Under steady-state conditions at pH 5 and 298 K, the second-order rate for the reaction of substrate (k_{cat}/K_m) is 3–4 times faster for [1-¹H]-glucose than for [1-²H]-glucose (Table 2). The k_{cat}/K_m values for [1-¹H] and [1-²H] 2-deoxyglucose are 860 and 120 M⁻¹ s⁻¹, respectively, revealing a primary KIE of 7. The rates are an order of magnitude slower than for the glucose [1-¹H] and [1-²H] for which k_{cat}/K_m is 8200 and 2600 M⁻¹ s⁻¹. The difference in the KIEs shows how C–H cleavage in the slower substrate has a greater contribution than substrate binding to its second-order rate constant. The reasoning is consistent with the observation that the unimolecular rate constant that controls turnover (k_{cat}) is more than order of magnitude faster for glucose (1200 s⁻¹) than for 2-deoxyglucose (50 s⁻¹) under the same conditions.

The degree to which bond cleavage limits the rate of sugar oxidation may vary with pH and with temperature depending on relative heights of energy barriers along the potential energy landscape. For oxidation of 2-deoxyglucose by glucose oxidase, the commitment to catalysis defined by Northrop as the ratio of the product-forming rate constant to the rate constant for substrate dissociation appears to be low and independent of pH. At pH 5, noncompetitive measurements with pure [1-¹H] and [1-²H] 2-deoxyglucose have allowed a direct comparison of k_{cat} to k_{cat}/K_m effects; these show that the isotope effect on k_{cat}/K_m approaches the intrinsic isotope effect on k_{cat} (¹H vs. ²H) 8. Thus, the rate-determining step in both the first- and second-order kinetic processes includes the cleavage of the bond to the anomeric carbon (the E·S to E·P step in Figure 4). Similar results at pH 9.0, where [1-¹H] 2-deoxyglucose reacts with $k_{\text{cat}}/K_m = 580 \text{ M}^{-1} \text{ s}^{-1}$ and exhibits ¹H versus ²H KIEs on both k_{cat}/K_m and k_{cat} of 7, indicate that bond cleavage represents the highest point on the energy landscape (Figure 4). This result has been confirmed by highly accurate KIEs measured using radiolabeled substrates under competitive conditions. Here the KIEs correspond to differential reactivity

Figure 4 Ping-pong kinetic scheme and energy landscape for the reductive half-reaction of glucose oxidase. The E•S and E•P are arbitrarily defined as being more stable than separated reactants and products.

Table 2 Rate constants and isotope effects under air saturation at 298 K

Substrate	$k_{\text{cat}}/K_{\text{m}} (M^{-1} s^{-1})$	$^L (k_{\text{cat}}/K_{\text{m}})$	$k_{\text{cat}} (s^{-1})$	$^L (k_{\text{cat}})$
[1- ^1H] glucose (pH 5)	$8.2 (1.9) \times 10^3$	3–4	$1.2 (0.3) \times 10^3$	~6

L represents ^2H or ^3H .

of isotopically labeled substrates in the same reaction solution. Isotope effects on $k_{\text{cat}}/K_{\text{m}}$ for 2-deoxyglucose at pH 9.0 and 298 K reveal that the ^3H substrate reacts 15.9 (0.5) times slower than the ^1H substrate and 2.44 (0.04) times slower than the ^2H substrate. From the above data, the calculated ^1H versus ^2H isotope effect on $k_{\text{cat}}/K_{\text{m}}$ is found to be 6.5 (0.5) close to the value derived from the noncompetitive measurements. Based on observed KIEs under a variety of conditions, it can be concluded that the observed k_{cat} reflects the free-energy barrier associated with the chemical step wherein sugar is transformed to lactone.

The kinetics of FADH^- oxidation by O_2 has also been analyzed using isotope effects. Solvent KIEs and heavy-atom KIEs on $k_{\text{cat}}/K_{\text{m}}$ for O_2 have been determined for high- and low-pH forms of glucose oxidase. The latter measurements were determined competitively by using isotope ratio mass spectrometry to follow the enrichment of ^{18}O in natural abundance O_2 as a function of reaction. The ratio of $k_{\text{cat}}/K_{\text{m}}$ for $^{16,16}\text{O}_2$ to $^{16,18}\text{O}_2$ ranges from 1.027(3) to 1.028(4) for the two enzyme forms. The KIE is close to the equilibrium isotope effect estimated using the Bigeleisen approach, which employs

gas-phase partition functions for O_2 and superoxide anion, the reactant and product of the rate-determining step. Solvent isotope effects accompanying O_2 reduction were found to be close to unity, showing that electron transfer, and not proton transfer, limits $k_{cat}/K_m(O_2)$. In addition, the observed isotope effects aid a direct comparison of rate constant for the enzymatic reduction of O_2 and the nonenzymatic reaction which in turn allows the extent of barrier lowering (catalysis) in the chemical step to be addressed.

Various types of KIEs have been used to elucidate the chemical mechanisms of glucose oxidase catalysis. The observed KIEs indicate that the rate of the chemical step can be extracted from the steady-state measurements using the slowly reacting substrate 2-deoxyglucose. The observed KIEs demonstrate rate-determining C–H cleavage in the reductive half-reaction and a rate-determining change in oxygen bond order upon electron transfer in the oxidative half-reaction. In addition to exposing which steps limit catalysis, KIE probes have been invaluable in demonstrating the role of the protein environment in facilitating catalysis.

Glossary

Activation Process that enhances transcription to boost cellular levels of regulated proteins.

Conformational change A significant rearrangement of atoms within a protein molecule in response to binding a specific small molecule (e.g., sugar binding by LacI).

Genome The entire DNA complement composing the genetic material of an organism.

Inducer A sugar that elicits LacI conformational rearrangement that releases operator DNA.

Induction The increase in *lac* enzyme production triggered by the presence of an inducer sugar.

Messenger RNA (mRNA) A copy of the DNA sequence that is used as a template for protein translation.

Operator The DNA sequence to which the repressor protein binds and thus inhibits RNA polymerase transcription.

Operon A region of bacterial DNA that is regulated as a unit, for example, the entire region encoding the *lac* repressor, metabolic enzymes, and regulatory regions.

Promoter The DNA sequence recognized by RNA polymerase for transcription initiation; in bacteria this region frequently contains a binding site for the catabolite repressor protein (CRP).

Repression The inhibition of transcription to maintain low levels of metabolic proteins/enzymes in the absence of appropriate conditions, such as lack of substrate for a metabolic pathway.

Repressor The protein that mediates inhibition of transcription by binding to a specific DNA sequence (see 'operator').

Transcription The act of copying the information encoded in DNA into a new mRNA molecule as a template for translation of the amino acid sequence of a protein.

Living organisms must sense a wide range of exogenous and endogenous stimuli in order to match gene expression to environmental state. From an energetic perspective, this process is most efficient at the point of DNA transcription into messenger RNA. The *lac* operon was the first system for which this mechanism was detailed and paved the way to discovering a variety of strategies for modulating RNA transcription. Regulation of *lac* operon expression allows bacteria to respond to changes in the availability of external lactose (milk sugar) and glucose concentrations by shifting production of enzymes used to metabolize lactose. In this manner, the bacteria are able to effectively utilize lactose when available and yet minimize energetic cost of producing metabolic proteins when lactose is unavailable. This article explores the historical context for the discovery of the prototypic lactose regulatory system and the structural features of the component proteins.

Historical Perspective

During the post-World War II years, at the Pasteur Institute in France, Jacques Monod and Francois Jacob were examining the

ability of bacteria to adapt to different sources of carbon as their energy source. They discovered that, when lactose (milk sugar) was absent from the growth medium, the bacterial enzymes that metabolize lactose were present at very low levels. When lactose was added, enzyme production increased ~1000-fold, a phenomenon termed 'induction'. (The three proteins encoded by the *lac* operon that import and metabolize lactose have historically been called 'structural' proteins and their coding regions 'structural genes'; however, we use the term 'metabolic' for these proteins and genes to distinguish them from later structural studies of the *lac* repressor and CRP proteins.)

Next, Jacob and Monod varied the molecular structure of lactose and the chemically related galactoside sugars and compared the consequent effects on growth and activity of *lac* metabolic proteins for *Escherichia coli* variants. They found that a subset of these sugars could induce but not be metabolized, and a different set could be metabolized but not serve as inducer. Thus, the function of inducing the *lac* metabolic proteins can be separated from the transport and metabolism of lactose. In the early 1960s, Jacob and Monod found that an inducer sugar functioned by relieving inhibition of

transcription for the metabolic genes. The inducible agent was finally identified as the lactose repressor protein, LacI. When the LacI protein was inactivated in the bacteria, the metabolic enzymes were always expressed at high levels, whether or not an inducer sugar was present. From these experiments, Jacob and Monod demonstrated that expression of RNA encoding an enzyme (or other protein) can be negatively controlled. This phenomenon of inhibiting transcription is termed 'repression'.

Further experimental observations indicated that, by itself, the presence of lactose does not always fully release repression for the *lac* operon. An additional factor contributing to the repression/induction balance was found to be glucose concentration. When glucose is abundantly available, full induction does not occur even in the presence of high lactose levels. From the cellular perspective, direct glucose utilization provides a more efficient energy source than converting lactose to glucose and galactose (and then galactose to glucose). Thus, in addition to repression by LacI, another regulatory mechanism must contribute to determining the level of *lac* enzyme expression. Two different mutations were discovered in the late 1960s/early 1970s that illuminated this issue, and a cell-free system was used to

demonstrate that one of these mutations disrupted the catabolite repressor protein (CRP) (cAMP receptor protein, also referred to as the catabolite activator protein, CAP). CRP binds the signaling molecule cAMP, which is, in turn, produced by the second protein identified in these mutagenesis experiments, adenylate cyclase. Adenylate cyclase activity is inhibited by high glucose concentrations. Together, CRP and adenylate cyclase provide a means to alter transcription by sensing glucose levels via detection of cellular cAMP concentrations. In contrast to the high specificity of the *lac* repressor (which only regulates the *lac* operon), the CRP/adenylate cyclase glucose sensor activates transcription of numerous systems in *E. coli* in its cAMP-bound form.

lac Operon

The region of the *E. coli* genome that is involved in lactose metabolism and control of *lac* gene expression is termed the *lac* operon. This region of DNA comprises sequences that contain several types of information – open reading frames

Figure 1 Schematic of the *lac* operon. The top horizontal bar depicts regions of the *lac* operon DNA: the promoter (P_i) for the tetrameric lactose repressor (*lacI* gene, '*I*'), the promoter (*p*) for the metabolic enzymes, the primary operator sequence LacO ('*O*', site for LacI binding), and the co-transcribed metabolic enzyme genes (*lacZYA*, '*Z*,' '*Y*,' and '*A*'). The cartoon of the functional cycle represents LacI tetramer (red ovals) binding to operator, LacI association with inducer (diamond) to form LacI-inducer complex (diamond inside yellow squares), LacI dissociation from operator (induction), RNA polymerase ('RNA pol') binding and transcription, and subsequent reassociation of LacI with LacO when sugar levels diminish. Shown at the bottom of the figure is the dimeric structure of CRP (teal rectangles), CRP association with cAMP (triangle) to generate CRP-cAMP complex (triangles inside purple rectangles), and CRP-cAMP binding within the promoter region to facilitate RNA polymerase binding and transcription. CRP dissociates from the promoter when glucose levels increase and cAMP levels fall. Changes in color/shape for protein symbols indicate conformational changes in response to binding the respective ligand (inducer or cAMP). Substitution of the *lac* metabolic genes by other protein coding sequences (prokaryotic or eukaryotic) allows effective control of specific protein expression using inducer/cAMP levels.

for two classes of proteins (metabolic and regulatory), 'promoter regions' that provide binding sites for RNA polymerase (the protein that transcribes DNA to mRNA), and binding sites for regulatory proteins. In order of their genomic appearance (Figure 1), the elements of the *lac* operon include:

1. the promoter for initiating transcription of *LacI*, followed by the *lacI* gene, which encodes the *lac* repressor protein (*LacI*);
2. the promoter for the *lac* metabolic genes involved in transporting and metabolizing lactose;
3. DNA-binding sites for *lac* repressor (*LacO*) and CRP that overlap this promoter; and
4. the genes for the *lac* metabolic proteins.

The latter encode proteins required for the transport and metabolism of lactose: β -galactosidase (*LacZ*), lactose permease (*LacY*), and thiogalactosidase transacetylase (*LacA*). Further discussion will focus on the functions and structures of the two regulatory proteins, *LacI* and CRP.

Lactose Repressor Protein

LacI Function

In the absence of available lactose, the role of *LacI* is to inhibit mRNA production for proteins encoded by the *lac*

operon. Transcription is not completely eliminated, but *lacZYA* mRNA is transcribed only at very low levels. This function is accomplished by *LacI* protein binding with high specificity and high affinity to the *lac* operator DNA sequence.

Transcription is subsequently inhibited via a variety of mechanisms. Since the *lac* operator (*LacO*) overlaps the promoter, *LacI* binding directly competes with RNA polymerase for binding this region. *LacI* can also impede transcription initiation and/or block elongation of mRNA to ensure effective transcription repression.

When lactose is available as a carbon source, the low levels of the metabolic protein *LacY* transport a small amount of lactose into the bacterium. Next, residual *LacZ* metabolizes lactose to glucose and galactose, which produces energy for the bacterium. Notably, this catalytic process also generates low levels of allolactose via a rearrangement of the β -1,4 linkage between glucose and galactose to a β -1,6 linkage (Figure 2). The by-product allolactose binds to *LacI* and elicits a conformational change in the repressor protein that results in release of the operator DNA sequence (induction). Consequently, RNA polymerase is freed to generate numerous copies of mRNA encoding the *lac* metabolic proteins. When translated into proteins, these metabolic proteins allow the bacterium to transport and metabolize large quantities of lactose as its carbon energy source, taking advantage of an environmental

Figure 3 Structures of LacI and CRP. Molecular graphics images were produced using the UCSF Chimera package from the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIH P41 RR-01081). (a) The tetrameric structure of the lactose repressor is shown in ribbons format; each monomer is a different color. This structure is from PDB file 1LBG. (This view does not show all of the atoms in the protein, since some are not resolved in the original structure.) DNA is shown at the top of the figure. Note that the dimer is the DNA-binding unit, whereas the monomer is the inducer-binding unit. The DNA-binding domain, hinge helices, core domain (with its N- and C-subdomains), and tetramerization domain are labeled. (b) Cartoon depicts the conformational change of a LacI dimer when it binds inducer. (c) The dimeric structure of CRP from PDB file 1RUN is shown with the sites for cAMP- and DNA-binding indicated. The DNA recognition helices (one per monomer) are also indicated. Two structures are known for apo-CRP (not bound to DNA or cAMP). Both structures show that the DNA recognition helices move significantly in the absence of cAMP binding, precluding effective contact with DNA. However, the two structures do not agree as to the final position of the helices.

opportunity. One result of the studies by Jacob and Monod was the discovery that a variety of non-natural galactoside sugars (e.g., IPTG; [Figure 2](#)) can induce LacI and relieve transcription repression of *lacZYA*. This discovery has been very important for biotechnology applications of this regulatory system.

LacI Structural Characteristics

Structural detail of the LacI protein has provided insight into the atomic-level mechanism by which this protein performs its functions. LacI is a multimeric, multidomain protein, an

arrangement now known to be typical for genetic regulatory proteins. LacI has four identical polypeptide chains (**Figure 3(a)**). Each polypeptide folds into distinct regions that have specific functions, and four monomers associate to form tetrameric LacI.

Folded protein domains can be isolated from the intact protein and maintain functions that are highly similar to the intact protein. For LacI, the N-terminal domain of a monomer, either with or without parts of the hinge-helix sequence, can be isolated by proteolysis. An isolated N-terminal domain can bind to one-half of LacO DNA with low affinity. If two of these domains plus the hinge-helix sequences are linked by a disulfide bond, this protein fragment binds to full-length LacO with very high affinity (but is not inducible by galactoside sugars). (Note that the LacO site is highly, but imperfectly, symmetric in sequence, therefore accommodating the two identical DNA-binding domains.) Only high-affinity binding by LacI represses mRNA transcription. Thus, the LacI dimer is the functional unit, and a LacI tetramer has two complete DNA-binding sites. Within the intact LacI–LacO complex, each N-terminal domain associates with bases in the DNA major groove, and the hinge helices insert into the minor groove to elicit a bend in the DNA (see **Figure 3(a)**).

The other product of proteolysis is the LacI core domain. This fragment is isolated as a tetramer, with each monomer comprised of two subdomains that flank the site for sugar binding. Thus, each monomer is able to bind an inducer molecule, creating four sugar binding sites per tetramer. (Note that the N- and C-subdomains within the core domain monomer are interconnected by multiple strands and cannot be separated by proteolysis.) When the inducer-binding site is occupied in full-length LacI, structural changes in the

N-subdomain affect the DNA-binding domain (**Figure 3(b)**). These alterations result in decreased operator-specific binding affinity; the inducer-bound repressor protein dissociates from the operator DNA site and is nonspecifically recruited to other regions of the genomic DNA.

The final domain of LacI is the C-terminal tetramerization domain, which connects two dimers via an antiparallel four-helix bundle (**Figure 3(a)**). When this domain is removed from the protein, the resulting LacI dimer is still capable of transcription repression. However, the amount of repression is decreased ~50-fold relative to that of tetramer LacI, for reasons described below.

Multiple Sites/Multiple Targets – DNA Looping

In addition to the primary operator, LacO, shown in **Figure 1**, two ‘pseudo-operator’ sequences are present within the *lac* operon sequence and contribute to repression. The DNA sequences of the pseudo-operators are very similar, but not identical, to LacO and are bound by LacI more weakly. The presence of two DNA-binding sites in LacI protein tetramer suggested a mechanism by which pseudo-operators could enhance repression – one LacI tetramer could bind two separate operators and generate a looped DNA structure. Experimental evidence for DNA looping has been obtained from a variety of laboratories. Recent evidence indicates that the angle between the two dimers must open for loop formation to occur, as illustrated in **Figure 4**. These looped structures are highly stabilized, accounting for the significant repression of *lacZYA* expression observed in bacterial cells. Indeed, DNA containing multiple operator sequences and with the supercoiling density characteristic of *E. coli* exhibits a half-life for the complex that exceeds 2 days. However, even these looped complexes respond rapidly (in less than 30 s) to the presence of inducer sugars, allowing quick adaptation to an external lactose source that may be transient.

Figure 4 Looped DNA structure. The teal blue curved line depicts the *lac* operon DNA (with shading to indicate nearness to observer), which contains three possible LacI-binding sites (two of which, O_1 and O_2 , are shown bound to LacI). The pseudo-operator sequence O_2 is located within the *lacZ* gene, and the primary operator sequence O_1 overlaps the promoter sequence for the *lacZYA* metabolic genes (**Figure 1**). Tetrameric LacI is shown at the bottom of the figure as simultaneously interacting with O_1 and O_2 . This structure loops the DNA and generates a complex with very high stability. Note that the dimers within a LacI tetramer separate and adopt a larger angle between them when looping between O_1 and O_2 than in the absence of looping (i.e., the structure shown in **Figure 3(a)**). The need for flexibility between the dimers for looping to occur is supported by experimental evidence.

Catabolite Repressor Protein

CRP Function

Bacteria find it energetically beneficial to utilize lactose only when glucose is unavailable. The *lac* operon thus has two regulatory switches, one for each sugar. Glucose levels are measured through a protein designated CRP. This monitoring system is indirect and occurs by detecting levels of a signaling molecule called ‘cAMP’ (**Figure 2**). cAMP is created by another protein called adenylate cyclase, and adenylate cyclase is directly regulated (inhibited) by high glucose. Thus, levels of glucose and cAMP are inversely related. As glucose levels decrease, cAMP levels rise, and cAMP binds to CRP. The CRP–cAMP complex has high affinity for specific target sequences within the bacterial genome (**Figures 1** and **3**). One of the DNA target sequences for cAMP–CRP is found within the promoter for the *lac* metabolic proteins, upstream of the *lac* operator sequence (**Figure 1**). Note that cAMP binding enhances CRP binding to DNA, whereas with LacI, sugar binding decreases the DNA binding. Another difference is that DNA binding by the cAMP–CRP complex enhances RNA polymerase transcription of *lacZYA* mRNA, whereas LacI binding represses it. The end result is that the proteins for lactose metabolism are

expressed at high levels only when environmental glucose is low and lactose levels are high.

CRP Structural Characteristics

Like LacI, CRP is multimeric and has multiple domains (Figure 3(c)). In this case, the CRP structure is dimeric, and each monomer comprises two domains. The N-terminal domain facilitates dimer formation and binds at least one molecule of cAMP (two/dimer). In the absence of cAMP, the two DNA-binding domains, one from each monomer, are not aligned properly for sequence-specific DNA recognition. In the presence of cAMP, the structure rearranges to bring the two DNA-binding helix–turn–helix structures into the proper orientation for effective DNA binding. Similar to LacI, CRP–cAMP binding also elicits a bend in the target DNA-binding site. Each monomer only binds to one-half of the DNA-binding site, which is symmetric through the center of the sequence. Indeed, the symmetry seen in the *lac* operon regulatory sites is a common feature of DNA regulatory binding sites, going hand in hand with the generally multimeric natures of these proteins.

Three Common Errors in Understanding the *lac* Operon

Several errors are encountered frequently in presentations of the *lac* operon. The most common error, propagated in multiple venues, is that lactose is the inducer that relieves LacI repression. As indicated in this article, the molecule that serves as inducer *in vivo* is a derivative of lactose, allolactose, that is generated by β -galactosidase as a side reaction in the cleavage of lactose to glucose and galactose (see Figure 2). This arrangement ensures that the inducer is not produced unless the metabolic potential to utilize lactose is present in the cell.

The second common error is that *lacZYA* mRNA is not produced at all in the absence of lactose (and hence the inducer allolactose). Even when no inducer is available, normal dissociation events of LacI from LacO allow a small amount of read-through by RNA polymerase, resulting in transcription of a very low level of *lacZYA* mRNA. This low-level transcription ensures that small amounts of lactose permease and β -galactosidase proteins are available to transport lactose and to generate allolactose for induction. This leaky transcription can be a problem when the LacI/LacO system is used to control recombinant protein expression: if the recombinant protein is toxic to *E. coli*, even tiny quantities can kill the growing bacteria. Thus, LacI/LacO regulation has been combined with other control systems (such as bacteriophage T7 polymerase) in order to exert a high level of repression while bacterial cultures grow to high densities, after which protein production is induced.

The third error is the assertion that induced LacI (bound to allolactose or gratuitous inducers) can no longer bind to the LacO operator. In fact, LacI inducer can bind to LacO, but the strength of the binding is greatly diminished. With this decrease in binding affinity, the LacI-inducer complex can no longer effectively discriminate LacO from the rest of the DNA in the bacterial genome. Since the genome is vastly larger than LacO (which represents only a very, very small fraction of the *E. coli* DNA sequence), the repressor protein is competed

away by this excess of nonspecific DNA, and RNA polymerase is able to transcribe *lacZYA*.

Implications for Complex Organisms

This simple bacterial regulatory system illustrates the complexity that can be generated with only two on/off switches. In fact, the response of this system is more analogous to a rheostat. Since the two protein switches respond to different signals, graded response occurs at intermediate ratios of glucose/lactose. Gene regulation in response to specific signals – whether related to environmental or internal changes – has a twofold advantage. The organism conserves energy/resources under conditions where gene expression would be useless (and expensive), but is able to selectively respond to a variety of input information. This type of regulatory control, with binding modulated by interactions with small ligands or other proteins, underlies the incredibly complex pathways by which gene expression is fine-tuned to create specific temporal, spatial, and environmental patterns in higher organisms.

Lectins

N Sharon[†] and H Lis, Weizmann Institute of Science, Rehovot, Israel

Published by Elsevier Inc.

Glossary

Glycan Any compound consisting of a few or many monosaccharides in free form or attached to another substance; it is referred to as a carbohydrate or saccharide.

Glycoconjugate A substance that consists of one or more glycans covalently attached to a noncarbohydrate constituent, typically protein (to give a glycoprotein) or lipid (forming a glycolipid).

Innate immunity A form of defense of animals and other organisms that acts against infection in the first minutes or hours. It is different from acquired or adaptive immunity that takes days or weeks to develop.

Mitogen A substance that stimulates cell division, especially of lymphocytes.

Lectins are a class of proteins that bind carbohydrates specifically and reversibly. They occur widely in animals, plants, and microorganisms, where their main function is to serve as cell recognition molecules. Their main use is for the detection, isolation, and characterization of glycoconjugates in solution as well as in and on cells.

Lectins (from Latin, *legere*, to select or choose) are referred to as proteins that combine with mono- and oligosaccharides reversibly and with high specificity, but are devoid of catalytic activity and, in contrast to carbohydrate-binding antibodies, are not products of an immune response. They are found in all classes of organisms, from viruses and bacteria to higher animals, including humans (Table 1) and occur in different shapes and forms (Figure 1). Hundreds of lectins have been isolated by affinity chromatography on immobilized carbohydrates, as well as by recombinant DNA techniques. The richest source of these proteins are plants, from the seeds of which several of the long-known proteins of this class – such as concanavalin A, phytohemagglutinin (PHA), and soybean agglutinin (SBA) – have been obtained. Most lectins are bi- or oligovalent with respect to carbohydrate binding; therefore, when they combine with sugars on the surface of cells, such as erythrocytes, they cause cross-linking of the cells and their subsequent precipitation, a phenomenon referred to as cell agglutination. The erythrocyte-agglutinating, or hemagglutinating, activity of lectins is a major attribute of these proteins and is used routinely for their detection and characterization. Lectins also possess the ability to precipitate polysaccharides or glycoproteins from solution; both the cell agglutinating and precipitating activities of lectins are inhibited by the sugars for which the lectins are specific.

Carbohydrate Specificity

Lectins are classified primarily into five specificity groups, according to the monosaccharide for which they exhibit the highest affinity: mannose, galactose/*N*-acetylgalactosamine, *N*-acetylglucosamine, fucose, and *N*-acetylneuraminic acid (sugars are of the D-configuration except for fucose which

is L). Relevant for the biological functions of lectins is the fact that, of the numerous monosaccharides found in nature, these six are typical constituents of the glycans present on the surfaces of eukaryotic cells. Some lectins specific for mannose also bind glucose, which differs from mannose in the configuration of the 2-hydroxyl, but only in rare cases they react with galactose, which differs from glucose in the configuration of the 4-hydroxyl. Lectins of the same specificity group may differ markedly in affinity for oligosaccharides or cells, while a few of them recognize only oligosaccharide derivatives of the above monosaccharides. Specificity for other sugars has been rarely encountered. The affinity of lectins to monosaccharides is usually weak, with association constants in the millimolar range, whereas that to oligosaccharides is often much higher, up to three orders of magnitude.

Molecular Properties

In general, lectins are oligomeric proteins of diverse structure and molecular size. They differ in primary, secondary, and tertiary structure, number of subunits and subunit assembly (Figure 2), metal requirement, as well as in the constitution of carbohydrate-binding sites. The polypeptide chains often consist of several molecular domains, only one of which is the carbohydrate recognition domain (CRD). Lectins belong to distinct protein families or superfamilies that share sequence homologies and similar tertiary and quaternary structures. These families are often of the same phylogenetic origin (e.g., the cereal lectins), although they sometimes cross phylogenetic barriers (as in the case of the structurally similar legume lectins that belong to different specificity groups and the galectins, animal lectins that bind exclusively β -galactosides, such as lactose and *N*-acetyllactosamine [$\text{Gal}\beta(1\text{--}4)\text{GlcNAc}$]). The C-type (Ca^{2+} -requiring) lectins are members of a superfamily of diverse specificities that include endocytic lectins, collectins, selectins, and siglecs, many of which are membrane bound. In collectins, the CRD is linked to a collagen-like region, whereas in selectins – E-selectin, P-selectin, and L-selectin – it is attached to an epidermal growth-factor-like domain and several short repeating units related to complement-binding

protein (Figure 1). The siglecs are a family of sialic-acid-specific cell-surface lectins with variable numbers of extracellular immunoglobulin-like domains and are thus members of the immunoglobulin superfamily. Bacterial lectins are typically in the form of fimbriae (or pili), hair-like submicroscopic appendages, consisting of an assembly of several different

types of subunits, only one of which has carbohydrate-binding activity, for example, for mannose (in type 1 fimbriae of *Escherichia coli* and *Klebsiella pneumoniae*) or galabiose, Gal α (1–4)Gal (in P fimbriae of *E. coli*).

Besides the surface lectins described above, a small number of soluble bacterial lectins have been described. These include

Figure 2 Structures of different lectins represented as ribbon diagrams. (a) Upper row shows monomers of lectins from different sources that share the jelly roll or lectin fold. First three lectins (from left) in the lower row all exhibit the β -trefoil fold. (b) Variations in quaternary lectins structures. The gray spheres represent metal ions; bound carbohydrate is shown in ball-and-stick representation. The diagram of SAP is from PDB entry sac. cyanovirin-N, an oligomannose-specific cyanobacterial lectin that is a potent inactivator of all strains of human immunodeficiency virus and simian immunodeficiency virus and has a potential for clinical use as an antiviral agent.

High-resolution X-ray crystallography of lectins in complex with their ligands and site-directed mutagenesis allowed the identification of the chemical groups on the protein and on the carbohydrate that interact with each other and of the types of bonds formed. These studies have shown that, like other carbohydrate-binding proteins, lectins combine with their ligands primarily by a network of hydrogen bonds and hydrophobic interactions; in rare cases, electrostatic interactions (or ion pairing) and coordination with metal ions also play a role. One or more water molecules sometimes mediate the bonding. Although in a single lectin a limited set of residues contribute to the formation of the bonds with the ligand, overall almost all kinds of amino acids participate in ligand binding.

Functions

Lectins possess numerous biological activities, nearly all of which are based on their ability to recognize and bind carbohydrates specifically (Table 2). In other words, as a result of their unusual capacity to decode the information encoded in carbohydrates, they act as recognition determinants in diverse biological processes. Thus, they function in cell–cell, cell–molecule, or molecule–molecule recognition. Influenza virus hemagglutinins A and B, lectins specific for *N*-acetylneuraminic acid (or hemagglutinin C specific for 9-*O*-acetyl-*N*-acetylneuraminic acid), as well as bacterial surface lectins mediate the binding of the pathogens to host cells, a prerequisite for initiation of infection. Inhibitors of bacterial lectins protect animals against experimental infection by the lectin-carrying organisms, providing a basis for attempts to develop anti-adhesion therapy of microbial infections. In some cases the bacterial lectins are responsible for the attachment to sugar residues on phagocytic cells, permitting the

Table 2 Lectin functions

Functions	Examples of lectins involved
<i>Microorganisms</i>	
Infectivity	<i>Escherichia coli</i> fimbriae; <i>Entamoeba histolytica</i> Gal/GalNAc-specific lectin; influenza virus hemagglutinin
<i>Plants</i>	
Defence	Snowdrop lectin, jacalin, wheat germ agglutinin
Symbiosis with nitrogen-fixing bacteria	Pea lectin
<i>Animals</i>	
Clearance of glycoproteins from circulation	Asialoglycoprotein receptor
Control of lymphocyte migration	Selectins
Control of glycoproteins biosynthesis	Calnexin, calreticulin, ERGIC-53
Innate immunity	MBLs, MMR, SP-A, SP-D
Complement activation	MBLs
Lectinophagocytosis	MMR, SP-A, SP-D
Modulation of cell-cell and cell-substratum interactions	Galectins
Modulation of signal transduction by B lymphocytes	Siglec-2
Neuronal myelination and regeneration	Siglec-4a and -4b
Targeting of glycoproteins to lysosomes	Man6P receptors
Tumor metastases	Galectins-1, -3, and -8; selectins

latter cells to kill the bacteria in the absence of serum factors, in a process designated lectinophagocytosis.

In plants, lectins may serve as defense agents against different kinds of phytopathogenic fungi and insects, as well as predatory invertebrates and vertebrates. They may also be involved in the establishment of symbiosis between nitrogen-fixing bacteria, mainly rhizobia, and leguminous plants, a process of cardinal importance both in the nitrogen cycle of terrestrial life and in agriculture.

The galectins are believed to function in cell adhesion. Their elevated levels on the surfaces of metastatic cancer cells may be responsible for the adhesion of these cells to target organs, a step necessary for metastasis formation. The mannose-6-phosphate (Man-6-P) receptors that are located intracellularly target lysosomal enzymes into the lysosomes. A defect in the synthesis of the Man-6-P marker on these enzymes results in I-cell disease (mucopolipidosis II or MLI). This is an inherited lysosomal storage disease, characterized by a lack of enzymes in the lysosomes that normally carry the marker, resulting in accumulation in these subcellular organelles of undigested glycoconjugates.

The endocytic lectins are responsible for the clearance from the circulatory system of glycoproteins (e.g., ceruloplasmin and α_1 -acid glycoprotein) from which terminal sialic acid has been removed, and possibly of cells too (e.g., aged erythrocytes or bacteria). A prominent representative is the mammalian

asialoglycoprotein receptor (or hepatic-binding protein) found on hepatocytes, specific for galactose and *N*-acetylgalactosamine. The mannose-specific lectin present on the surface of macrophages (MMR) has been implicated in antimicrobial innate immunity. It binds infectious organisms that expose mannose-containing glycans on their surface, leading to their killing. The soluble mannose-binding lectins (MBLs) of mammalian serum and liver and the pulmonary surfactant proteins A and D (SP-A and SP-D), all members of the collectin family, also function in innate immunity. MBL deficiency syndrome is associated with recurrent, severe bacterial infections in infants; it is caused by a mutation of a single amino acid in the collagen-like domain of the lectin. The selectins mediate the adhesion of circulating leukocytes to endothelial cells, a prerequisite for their extravasation into other tissues. They thus control the migration (homing) of lymphocytes to specific lymphoid organs and of leukocytes to sites of inflammation, where they act to eliminate bacteria and other foreign intruders. Individuals unable to synthesize oligosaccharides recognized by the selectins, such as sialyl-Le^x [NeuAc α (2-3)Gal β (1-4)[Fuc α (1-3)]GlcNAc] (as seen, for example, in cases of leukocyte deficiency type II (LADII)), suffer from recurrent microbial infections. The mechanism that helps leukocytes to break the endothelial barrier as a step in the fulfillment of their infection-fighting duties, is also responsible for their undesirable accumulation in tissues where they do not belong (e.g., joints), thereby causing damage, swelling, and pain. In reperfusion injury, which may occur after heart infarct or cerebral stroke, the accumulated leukocytes destroy tissues that have been damaged by temporary lack of oxygen. As shown in experimental animals, sialyl-Le^x attenuates myocardial necrosis after myocardial ischemia and reperfusion, another example of the great potential of antiadhesion therapy. In addition to their involvement in inflammation, the selectins may play a role in the attachment of the human blastocyst to the uterine lining and in the spread of cancer cells from the main tumor throughout the body to form metastases. The singlens have been implicated in cell-cell interactions in the immune system and in the process of mediation. Intracellular lectins such as connexin, calreticulin, and ERGIC-53 participate in the control of glycoprotein biosynthesis.

Applications

Lectins, mainly those from plants, are invaluable tools for detection, isolation, and structural and functional investigation of complex carbohydrates, especially glycoproteins. In immobilized form, for example, covalently bound to Sepharose, they are indispensable for purification and isolation by affinity chromatography of glycoproteins, glycopeptides, and oligosaccharides. Lectins are also useful as histochemical and cytochemical reagents: derivatized with fluorescent dyes, gold particles, or enzymes they serve for the detection of glycoconjugates in tissue sections and on cells, as well as on and in subcellular organelles, mainly for examination of changes that occur on cell surfaces and in cells during physiological and pathological processes, from differentiation to cancer.

An important recent addition to the armament of lectin-based analytical tools is that of microarrays. These microarrays consist of discrete probes of tiny spots of lectins with different specificities immobilized on a solid support such as glass or nitrocellulose. When charged with a fluorescent glycoprotein (or similarly labeled cells) a pattern characteristic for the glycoprotein is observed providing information on the structure of its glycans.

A few lectins are employed in blood typing, for example, those of the seeds of *Lotus tetragonolobus* and *Ulex europaeus* for the identification of type O cells, and of secretors of blood group substances. PHA and concanavalin A are potent *in vitro* T-lymphocyte mitogens, while another lectin, pokeweed mitogen, stimulates both T and B cells. Mitogenic stimulation by lectins provides a simple means to assess the immunocompetence of patients and to monitor the effects of immunosuppressive and immunotherapeutic treatments, as well as to prepare chromosome maps for karyotyping, sex determination, and detection of chromosome defects.

Selective agglutination by PNA permits the facile separation of mouse and human cortical (immature) thymocytes from the medullary (mature) ones. Treatment with SBA removes mature T cells from human bone marrow and affords a fraction enriched in stem cells. Lectin-purged bone marrow of haplo-identical donors serves routinely for transplantation into children born with severe combined immune deficiency (bubble children) with close to 75% success. The method was also used experimentally in the 1980s for bone marrow transplantation of leukemia patients. Knowledge of the properties of lectins was essential for the development of enzyme replacement therapy for the treatment of Gaucher disease; there is hope for lectin replacement therapy for patients with defects in innate immunity, for example, MBL-deficient patients.

A major application of toxic lectins, such as ricin, is for the selection of resistant animal cell lines. These cell lines provide access to glycoproteins with modified glycan structures and to novel glycosyltransferases. They are useful tools for the investigation of the mechanism of protein glycosylation and for the large-scale production of therapeutic glycoproteins with desired carbohydrate structures.

Glossary

Autoregulation A gene product regulates expression of its own gene.

Chromatin immunoprecipitation Technique used to precipitate a protein antigen using specific antibody to identify protein–DNA interactions at the genome level.

DNA microarrays A surface carrying an array of probes, DNA oligonucleotides corresponding to genes of interest, which are hybridized with cDNA from RNA isolated from cells under a given condition.

Operator Specific DNA site where transcription factor binds and modulates initiation of gene transcription.

Promoter Sequence located upstream of a gene to which RNA polymerase binds to initiate transcription.

Regulon Group of genes whose expression is regulated by a common regulator(s).

Repressor Protein that inhibits gene expression by sterically interfering with binding of RNA polymerase or by binding to RNA.

Introduction

The *Escherichia coli* LexA regulon is a regulatory network, encompassing at least 57 genes whose products govern a coordinated bacterial response to DNA damage. The induced LexA regulatory system has also been designated the SOS response to emphasize its role in the cellular response to distress. The expressed SOS functions not only repair DNA damage but also enhance adaptation through mutagenesis and genetic exchange. The SOS response thus plays a broad role, modulating evolution and dissemination of drug resistance and virulence factor genes, as well as the synthesis and secretion of virulence factors. In addition, the SOS system controls persistence and multidrug tolerance in a subpopulation of bacterial cells. The SOS system is widespread among bacteria but exhibits considerable variation with regard to its components and regulation. This article outlines regulation by LexA in *E. coli*, which is the best-understood SOS system and has been studied most extensively.

The *E. coli* LexA Regulatory System

Control of gene expression in response to environmental assaults, and the maintenance of the structural and functional integrity of the genome are essential for cell survival. The bacterial SOS system is an inducible DNA repair and damage-tolerance response triggered either by extrinsic treatments that elicit DNA damage or by intrinsic events that disrupt DNA replication.

A comprehensive response to DNA lesions was first described in detail in *E. coli*. Evelyn M. Witkin postulated that cellular filamentation and phage induction are regulated by a common repressor, which is inactivated in response to DNA damage. In the 1970s, Miroslav Radman proposed that a coordinated cellular response controlled by the interplay of two key proteins, a repressor and an inducer, is mounted

upon DNA damage. The product of the *lexA* gene (locus for X-ray sensitivity A) is the repressor of the regulon while recombinase A (RecA) is involved in sensing DNA damage and induces inactivation of the LexA repressor. During normal bacterial growth, LexA downregulates expression of its own gene and, in *E. coli*, the expression of more than 50 unlinked genes. In response to DNA damage, RecA (bound to adenosine triphosphate (ATP)) polymerizes onto single-stranded DNA (ssDNA) exposed upon repair or replication of damaged DNA, creating a helical nucleoprotein filament. The active ssDNA–ATP–RecA filament (RecA*) interacts with LexA and activates its latent self-cleaving activity. Cleavage inactivates LexA, instigating repressor dissociation from its DNA targets (SOS boxes) and induction of the LexA regulon. Subsequently, as DNA damage is repaired or bypassed, the level of ssDNA, the SOS-inducing signal, decreases and the co-protease activity of RecA filaments disappears (note, RecA* does not participate directly in the proteolysis reaction but instead stimulates LexA cleavage and is thus termed a ‘co-protease’). Functional LexA rapidly re-accumulates, returning the system to its repressed state (Figure 1).

Defining the LexA Regulon

Genes of the SOS regulon are characterized by (1) basal-level expression during normal bacterial growth and induction following DNA damage; (2) absence of induction in the *lexA* (*ind*) mutant strain with noncleavable LexA protein; (3) constitutive induction in strains carrying the *lexA* (*def*) allele, due to impaired repressor dimerization and unstable DNA association; and (4) promoter regions that carry DNA targets that resemble the conserved LexA operator sequence.

The first investigations to show that the SOS response is a global genomic response to DNA damage were performed in Graham C Walker’s laboratory. Through random insertion of a *lacZ* reporter gene into the *E. coli* chromosome, they

Figure 1 An overview of the SOS response in *E. coli*. In the uninduced state, LexA repressor binds to the promoter regions of SOS genes and sterically precludes their transcription. The polymerase III holoenzyme (Pol) carries out DNA replication. In the induced state, at the site of DNA damage PolIII arrests, ssDNA accumulates and active RecA filament is formed. Due to induced LexA self-cleavage, specifically bound LexA repressor dissociates from operators, leading to de-repression of SOS genes. Subsequently, as DNA damage is repaired, SOS induction is reversed. Adapted from Butala M, Žgur-Bertok D, and Busby SJW (2009) The bacterial LexA transcriptional repressor. *Cellular and Molecular Life Sciences* 66: 82–93, with permission from Springer Basel AG.

identified genes whose expression was induced following DNA damage. Characterization of genes upregulated in a *recA*/*lexA*-dependent manner revealed a 20-base-pair consensus LexA-binding site in promoter regions of SOS genes. Whole genome technologies that use microarrays to analyze transcriptome or chromatin immunoprecipitation experiments have now identified the full catalog of genes regulated by LexA. While the roles of most of the newly identified LexA-regulated genes are still unknown, unraveling their particular functions will yield insight into the molecular mechanisms underlying the SOS response. Several gene transcripts are decreased following DNA damage and some, while exhibiting a similar expression profile as genes of the LexA regulon, are not directly regulated by LexA. It thus seems that the SOS response is part of a larger, coordinated response network.

The LexA Regulatory System in the Repressed State

LexA exerts repression by binding to target sites located near promoters of SOS genes, blocking access of RNA polymerase. The C-terminal domain (CTD) of LexA is involved in dimerization and the N-terminal domain (NTD) in DNA binding. Intact LexA dimerizes by the CTD, and binds to DNA via a helix–turn–helix in its NTD (**Figure 2**).

LexA binding motifs are conserved in many Gram-negative bacteria. The consensus DNA target in *E. coli* is a palindromic dyad taCTGT-(at)₄-ACAGta and is designated the LexA box or

Figure 2 Model of the *E. coli* LexA repressor bound to the operator DNA site. LexA dimerises by the carboxy-terminal domain, and interacts with DNA by the amino-terminal domain. The two domains are linked by a flexible hinge region. Adapted from Butala M, Žgur-Bertok D, and Busby SJW (2009). The bacterial LexA transcriptional repressor. *Cellular and Molecular Life Sciences* 66: 82–93, with permission from Springer Basel AG.

SOS box. Functional LexA repressor is a homodimer while intracellular monomer levels are very low. Each of the two symmetrically inverted DNA-binding elements accommodates one LexA subunit. For stable and specific DNA binding, a

conformational change in LexA must occur. Binding to consensus targets with dyad symmetry requires LexA subunit–subunit interactions that enable high specificity and stabilizes interactions with both halves of the DNA duplex.

The LexA box exhibits considerable diversity; thus, no two sequences are alike and LexA binds with different affinities to the various variants enabling differential induction of the LexA regulon genes. The location of SOS boxes at promoters varies with respect to the transcription start site; some are positioned between the –35 and –10 elements, some overlap with the promoter elements, while others are adjacent to the target promoter. Although most *E. coli* LexA regulon genes possess a single LexA operator site, the number can range up to three SOS boxes. For example, the promoter region of the *lexA* gene carries separated tandem operators. LexA autoregulation sets a control of its own intracellular level via a feedback mechanism, enabling a rapid response to even small amounts of the inducing signal.

Triggers of the SOS Response

SOS genes can be induced by diverse exogenous treatments such as irradiation or chemicals, and can also be induced by DNA damage, caused by metabolic intermediates within the cell, by stalled replication forks, or by defects following recombination or chromosome segregation. Physical stress, such as high pressure that induces activity of the type IV restriction endonuclease, and even certain antibiotics, most notably fluoroquinolones such as ciprofloxacin, are also known to induce the SOS response. Note that the SOS-inducing signal is persistent regions of ssDNA that are generated when growing cells attempt to replicate damaged DNA. Depending upon the nature of the inducing signal, either the RecBCD or the RecFOR complex expose ssDNA to RecA.

The SOS response can also be triggered independently of RecA at low intracellular pH when LexA forms aggregates, which results in induction of LexA-repressed genes. Transient

failure of pH homeostasis occurs in *E. coli* upon shifts of extracellular pH or in mutants with improper intracellular pH regulation. Presumably, this is a bacterial survival strategy when crossing the gastric acid barrier.

Sensing the Signal and Inducing LexA Inactivation

The major SOS-inducing signal is the accumulation of ssDNA. During normal growth a limited amount of ssDNA is tolerated; however, above this threshold, the SOS system is induced in a LexA-dependent manner. Long-lived ssDNA is protected and stabilized by the ssDNA-binding (SSB) protein. Tetrameric SSB migrates along ssDNA, transiently melting short DNA hairpins and stimulating RecA filament elongation on DNA. Association of ATP-liganded RecA protomers constitutes an activated nucleoprotein filament (RecA*) (Figure 3). RecA-mediated SOS induction requires an extended filament conformation but no ATP hydrolysis (note that RecA protein besides working as a co-protease and activator of the DNA polymerase V plays a central role in recombination and is involved in a surprising range of other reactions in *E. coli*).

LexA is recognized by proteases only following self-cleavage, when otherwise latent protease recognition signals are exposed in the cleaved fragments. The self-cleavage of LexA generates LexA N- and C-terminal fragments of 83 and 118 amino acids, respectively. The fragments are rapidly degraded by the ClpXP protease and the degradation of the cleaved C-terminal fragment is facilitated by the Lon protease. Proteolysis ensures proper regulation of induction of the SOS response, since the LexA N-terminal fragment, that contains the DNA binding domain, still retains some repressor function.

Insights into the Key Step in the SOS Response

The LexA repressor is stable in normal growing cells, with a half-life of nearly 1 h. *E. coli* contains approximately 1300 LexA

Figure 3 Crystal structure of the active *E. coli* RecA filament (pdb ID: 3CMU), the front (a) and the side view (b). The six RecA protomer monomers (numbered) form a filament on the 18 nt ssDNA (nucleotides are in yellow). ADP–aluminum fluoride–Mg (ADP–AF₄–Mg) is a nonhydrolyzable ATP analog. ADP–AlF₄–Mg is sandwiched between two adjacent RecA protomers (ADP in yellow, Mg in red). Dotted arrow indicates deep helical groove. Figure prepared with visual molecular dynamics (VMD). Reproduced from Humphrey W, Dalke A, and Schulten K (1996) VMD: Visual molecular dynamics. *Journal of Molecular Graphics* 14: 33–38.

molecules. Repressor self-cleavage commences approximately 1 min after exposure to UV and, after 5 min, the level of LexA falls 10-fold. Self-cleavage takes place only after LexA has dissociated from its target, since dimers that are bound at specific operator targets cannot be inactivated.

Upon LexA interaction with the deep helical groove of RecA*, intramolecular cleavage of the repressor occurs. LexA is specifically cleaved at its Ala84–Gly85 bond. John W Little and colleagues proposed a Ser–Lys dyad mechanism for LexA autodigestion. The uncharged form of Lys156 helps remove a proton from the Ser119 hydroxyl group, which then acts as a nucleophile to attack the Ala84–Gly85 bond (Figure 4). *In vivo* cleavage requires RecA but, *in vitro*, it can proceed independently of RecA at alkaline pH (a reaction termed autocleavage).

Crystal structures of LexA mutants revealed that the cleavage site can adopt two conformations. In the cleavable state, the cleavage site is located adjacent to the catalytic center, the Ser119–Lys156 dyad, while in the noncleavable conformation it is ~20 Å away from the active site. It has been suggested that interaction with RecA* induces a conformational change in LexA and deprotonation of Lys156. It was also suggested that RecA* may preferentially interact with and stabilize the LexA cleavable state. However, recent evidence suggests that RecA* can bind to LexA in both the cleavable and noncleavable states. Residue Lys156 is solvent exposed and likely protonated in the LexA noncleavable conformation. The energetic cost of burying the charged group of Lys156, which is required for cleavage, provides another layer of regulation of LexA cleavage and helps to prevent autodigestion. Thus, by acting as a co-protease, RecA inactivates LexA, thereby inducing its expression, together with more than 50 other SOS gene products.

DNA Damage Repair

The level, timing, and duration of expression of each individual LexA regulon genes differ significantly. Most genes of the LexA regulon, including *recA*, are, in the absence of induction, expressed at a basal level. Specifically bound LexA molecules cannot be inactivated, which accounts for the precise timing of expression of the SOS genes following induction. Genes with high-affinity SOS boxes are expressed late in the SOS response due to a persistent decrease in the intracellular LexA pool. On the contrary, selective derepression of SOS genes with weaker operators occurs in response to minor inducing signals.

The SOS response is characterized by temporal control. Initially, SOS products (*recA*, *ssb*) sense DNA damage to protect and maintain the structural integrity of the replication fork. The LexA repressor is also induced immediately. Active RecA* initially signals the upregulation of SOS genes involved in high-fidelity DNA repair. Early induced genes include nucleotide excision repair genes *uvrA*, *uvrB*, *uvrD* that enable single-strand repair catalyzed by the UvrABCD proteins. To facilitate the resumption of processive replication, genes *recA*, *recN*, *ruvAB* of recombinational repair are induced. In order to circumvent lesions that inhibit DNA replication even after enhanced recombinational repair, low-fidelity DNA damage tolerance pathways are induced and DNA polymerases, PolIII (*polB*), PolIV (*dinB*), PolV (*umuC*, *umuD*) that operate in a poorly processive and error-prone manner are synthesized. Their ability to perform translesion DNA synthesis, allows a lethal event to be bypassed and replication to recover. These polymerases are the main contributors to SOS mutagenesis, which is an active process.

Precise temporal modulation of SOS gene expression is coordinated with DNA repair processes and influences many other

Figure 4 Two distinct conformations of the LexA cleavage site region and a detailed view of the active site. (a) Cleavage site region in the noncleavable state (pdb ID: 1jhh, chain A) is presented in blue and the CTD (pdb ID: 1jhe, chain A) in the cleavable state in red. The catalytic dyad, Ser119 and Lys156, is presented as a stick model and cleavage site Ala84–Gly85 as a ribbon presentation in yellow. (b) Model of the LexA self-cleavage mechanism. Neutral base Lys156 activates the nucleophile LexA119. Hydroxyl group of the activated nucleophile attacks the carbonyl carbon of the scissile peptide bond (arrow), followed by the transfer of the proton to the newly generated amino group (dotted line). The figure was generated by VMD and adapted from Butala M, Žgur-Bertok D, and Busby SJW (2009) The bacterial LexA transcriptional repressor. *Cellular and Molecular Life Sciences* 66: 82–93, with permission from Springer.

cellular processes. Damage inflicted on bacterial DNA leads to fast and massive intracellular coaggregation of RecA and DNA into a lateral macroscopic assembly. These intracellular assemblies are the functional target for DNA repair and are responsible for protection of the cell's DNA heritage.

Cell-Cycle Checkpoints

The expression of SOS genes is turned on in a pattern of discrete activation pulses; therefore, the system is not simply induced and turned off when DNA damage is repaired. To prevent the overlap of cell-cycle processes, the SOS system regulates DNA damage and cell division checkpoints.

E. coli cell-cycle checkpoints are regulated by the *umuDC* and *sulA* gene products. Uncleaved UmuD₂ in complex with UmuC activates a DNA damage replication checkpoint. UmuD₂C inhibits DNA synthesis directly by associating with the DNA replication complex. If high-fidelity repair is insufficient, the UmuD'₂C complex, PolV polymerase, is formed. Following SOS induction, dimeric UmuD is converted to functionally active UmuD' by RecA*-induced self-cleavage that is similar to inactivation of LexA. However, RecA*-mediated self-cleavage of UmuD is much slower than self-cleavage of LexA, providing time for accurate repair prior to recovery of replication by translesion DNA synthesis. The UmuD'₂C complex is activated by interacting with a single RecA-ATP transferred from the RecA* filament. Translesion DNA synthesis by the PolV polymerase enables replication over any remaining DNA lesions.

During the DNA repair process, cell division is inhibited which leads to the formation of cellular filaments. Notably, upon damage to the genome, the LexA-regulated *sulA* gene product is highly expressed and interacts with the FtsZ protein, involved in septum formation prior to cell division. Most likely, this checkpoint serves to delay cell division until DNA damage has been repaired. In addition, by inhibiting cell division the two daughter chromosomes are not separated enabling recombinational repair.

Turning Off the SOS Response

Once DNA damage is repaired and replication resumed, the co-protease activity of RecA disappears resulting in re-accumulation of LexA and repression of the SOS genes. Intracellular proteolysis of SOS gene products is also triggered to control and restrict their activity during the repair and recovery phases of the SOS response respectively.

Members of the LexA Super-Family

Jeffrey W Roberts and colleagues demonstrated that exposure of lysogens containing bacteriophage λ to DNA-damaging treatments results in RecA-mediated cleavage of the λ CI repressor. SOS regulation enables temperate λ -like bacteriophages to sense the physiological condition of the host cell and switch the phage from lysogenic to lytic growth. LexA, UmuD, and several λ CI-like repressors, exhibit CTD homology and undergo completely parallel cleavage reactions in helical

groove of the RecA* filament. Self-cleavage of LexA is intramolecular while UmuD is cleaved in an intermolecular reaction. Note that upon self-cleavage, dimeric UmuD is converted to the functionally active UmuD', in contrast to repressors that are inactivated by cleavage. Remarkably, compared to LexA, RecA* catalyzes slow self-cleavage of the CI repressor and UmuD; hence, prophage induction and mutagenesis are induced only when DNA is severely damaged.

Plasmid-Encoded Genes of the LexA Regulon

Some plasmid-encoded genes, with broader functions than defense against DNA damage and adaptation through mutagenesis, are also part of the LexA regulon. For example, colicins are plasmid-encoded bacteriocins, synthesized by and active against *E. coli* strains and its close relatives. Colicins are released into the environment only after lysis of the host cell. Expression of operons encoding colicin functions are always strongly repressed by LexA, and slow dissociation from the operators may account for the late induction of colicin genes during the SOS response. RecA-mediated production of bacteriocins thus resembles prophage induction, leading to cell lysis upon persistent, high level DNA damage. Many colicins can promote genetic diversity in *E. coli* populations pointing to a role in evolution.

The *qnr* genes, which encode fluoroquinolone-resistance determinants, provide another example of plasmid-borne LexA-repressed genes. These are widespread in Enterobacteriaceae and are all directly regulated by LexA. Since fluoroquinolones induce self-cleavage of LexA, this is the first example of SOS-dependent regulation of an antibiotic-resistance mechanism in response to the antibiotic itself.

Bacterial LexA Regulon Diversity

Although the SOS system is highly conserved among bacteria, the genes controlled by LexA, their regulation and consensus LexA-binding sites differ significantly. In *Bacillus subtilis* LexA regulates 26 operons encompassing 63 genes (note that the *B. subtilis* LexA protein is also designated DinR). In comparison, the *E. coli* LexA regulon comprises 57 genes and has only eight orthologs in *B. subtilis*. To further illustrate the diversity found in SOS networks, in both *Rhodobacter sphaeroides* and the cyanobacterium *Synechocystis* sp., the LexA paralogue can function both to repress and to activate transcription.

The Virulent Side of the SOS Response

Besides high-fidelity repair pathways, SOS genes encode low-fidelity translesion DNA polymerases (in *E. coli*, PolII [*polB*], PolIV [*dinB*], and PolV [*umuC*, *umuD*]) that enable bacteria to increase their mutation rate in times of stress. Studies employing therapeutic drugs showed that low or subinhibitory concentrations of certain antibiotics, that interfere with DNA replication as well as cell wall synthesis, can trigger the SOS response. Hence, antibiotics can accelerate evolution by, for example, the acquisition of point mutations that result in inactivation or efflux of the drug.

SOS-inducing antibiotics also affect virulence in several pathogenic bacteria. Antibiotics that activate RecA*-mediated inactivation of LexA also trigger self-cleavage of phage repressors of resident prophages in *E. coli*, *Vibrio cholerae*, and *Staphylococcus aureus*. Consequently, certain antibiotics promote the horizontal spread of temperate phage and associated pathogenicity islands. In addition, the lateral transfer of integrating conjugative elements, for example, the *V. cholerae* SXT element encoding antibiotic resistance, can be induced. Thus, SOS-induced mobilization and high-frequency horizontal transfer of DNA elements accelerate the spread of virulence factors and drug resistance genes. In *E. coli*, induction of the LexA regulon has been shown to be required for the acquisition of resistance to ciprofloxacin and rifampicin. In addition, recombination of integrons, genetic elements capable of incorporating and expressing promoterless genes, was shown to be controlled by the SOS response.

Cells in a bacterial population can survive antibiotic stress by forming dormant cells, designated as persisters that are highly tolerant to antibiotics. Persisters are not mutants but rather phenotypic variants of sensitive cells. Recently, a small membrane-acting peptide encoded by the LexA-regulated gene, *tisB*, was suggested to control persister formation.

Distinct from drug-induced mobilization of DNA elements, the SOS system also induces chromosomal virulence gene expression. For example, prophage encode the *E. coli* Shiga toxin. In enteropathogenic *E. coli*, SOS regulates a type III secretion system responsible for secretion of virulence-associated factors into host cells. Interestingly, in some *S. aureus* strains, a

LexA-regulated gene encodes the fibronectin binding protein (FnBB) that mediates tissue attachment and the establishment of infection.

Glossary

Ionotropic glutamate receptors This general class of glutamate receptors represents ligand-gated, ion-channel-forming receptor complexes in neuronal membranes. Channel activation occurs following the application of L-glutamate or one of its analogs. This class of receptors is further subdivided into three families of receptor-ion channels based on their sensitivity to select agonists.

Long-term depression (LTD) Synaptic plasticity that occurs following low-frequency stimulation of synapses and which manifests itself as a decreased response to a subsequent single stimulus applied to the same synapses.

Long-term potentiation (LTP) Synaptic plasticity that occurs following high-frequency stimulation of synapses and which manifests itself as an increased response to a subsequent single stimulus applied to the same synapses.

Metabotropic glutamate receptors A class of G-protein-coupled glutamate receptors in neuronal membranes. These receptors may either activate phospholipase C or inhibit adenylyl cyclases, and they do not directly activate ion channels. This class of receptors is further subdivided into three groups, referred to as groups I–III, based on their sensitivity to select agonists and antagonists.

Synaptic plasticity The adaptive changes in neurotransmission across synapses occurring as a result of repeated stimulation of a set of synapses. The changes in the electrical response of a set of synapses to a single stimulus applied after the delivery of a series of high-frequency repetitive stimuli can last for many hours or many days. These changes in synaptic efficacy are accompanied by alterations in gene transcription, protein synthesis and enzyme, ion channel, and receptor activity.

The mammalian central nervous system (CNS) has a great capacity to adapt to many stimuli and perturbations of normal physiological function and this adaptability or plasticity is crucial in coding, storing, and retrieving information. Over the past decade, it has become clear that transient elevations of intracellular calcium (Ca^{2+}) in neurons represents the key signals used by nerve cells to alter their molecular structure and function and to produce long-lasting changes in cell function. These Ca^{2+} -activated molecular events are crucial not only for phenomena such as learning and memory but also for determining neuronal survival or damage. Key regulators of Ca^{2+} entry into neurons are the receptors for the excitatory neurotransmitter, L-glutamic acid.

Calcium Signaling in Neurons

Adaptation of brain function to incoming stimuli or to altered behavioral states is a well-demonstrated phenomenon. Such adaptation is thought to involve long-lasting alterations in the sensitivity of select neuronal networks or select synapses of individual neurons. The phenomenon of long-lasting changes in synaptic activity in neurons is, in part, the result of altered gene transcription and protein synthesis. Changes in the concentration of free intracellular calcium (Ca^{2+}) brought about either through influx into nerve cells or release from intracellular stores are considered to be the major signals for such adaptive changes in neurons. Under normal physiological conditions in unstimulated neurons, the concentration of free intracellular Ca^{2+} ($[\text{Ca}^{2+}]_i$) is maintained at ~45–75 nM, that is, a concentration that is ~10 000-fold lower than that in the extracellular environment of neurons. Following the stimulation of neurons, through either synaptic

activation, primarily of glutamate receptors (but also of other receptors, such as nicotinic acetylcholine receptors (AChRs)), or direct electrical stimulation, the intracellular levels of free Ca^{2+} can change quite rapidly and substantially, as described below (Figure 1).

The low free $[\text{Ca}^{2+}]_i$ is maintained through buffering mechanisms that are dependent on the activity of both Ca^{2+} -transport systems and Ca^{2+} -binding proteins present in neurons. Both of these Ca-buffering processes are important in reestablishing low free $[\text{Ca}^{2+}]_i$ following perturbations of the concentrations after synaptic activation and membrane depolarization of neurons. Among the buffering mechanisms, the transport carriers either pump Ca^{2+} out of the intracellular environment, such as the plasma membrane ($\text{Ca}^{2+} + \text{Mg}^{2+}$)-ATPase (PMCA) and the $\text{Na}^+ - \text{Ca}^{2+}$ exchange carriers (NCX), or sequester Ca^{2+} in intracellular compartments, such as the endoplasmic reticulum, through the activity of the sarcoplasmic/endoplasmic reticulum Ca-ATPase (SERCA), and the mitochondria, through the activity of the mitochondrial Ca^{2+} uniporter (Figure 1). Calcium-binding proteins (Ca^{2+} BP) that have been shown to buffer intracellular Ca^{2+} include parvalbumin and calbindin as the primary Ca^{2+} -buffering proteins in neurons, as well as many other Ca^{2+} -binding proteins, such as calmodulin, calyphosine, neurocalcin, hippocalcin, and visinin-like protein 3.

Electrical stimulation of neurons with a stimulus of sufficient magnitude to depolarize the cell membrane from the normal electrical potential of ~−70 mV internal negative to a potential that is 10–20 mV or more, less negative internally, can trigger the initiation of a regenerative, self-propagating form of membrane depolarization that usually starts in the region where the axon process of a neuron emerges from the cell body and travels down to the fine terminal branching

Figure 1 Pathways of Ca^{2+} entry, extrusion, and sequestration in neurons.

points of the axon (Figure 2). This self-propagating depolarization, known as an 'action potential', depends on the rapid opening of voltage-gated sodium channels (VGSCs).

Depolarization of the nerve terminal region of a neuronal axon by an action potential leads also to the opening of voltage-gated Ca^{2+} channels (VGCCs) in the axon terminal region. VGCCs allow for the rapid entry of Ca^{2+} from the extracellular environment, an event that is crucial for the first step in the transformation of the electrical event that has traveled down the axon to a chemical-signaling event, that is, the release of chemical transmitters. The molecular events that lead to Ca^{2+} -induced exocytosis of transmitter molecules stored within synaptic vesicles at the nerve terminal are progressively being defined through biochemical, biophysical, and genetic studies but are not discussed further here.

Action potentials initiated at the beginning of the axon as it exits the cell body spread in two directions, toward the axon terminal as described above, as well as toward the cell body and the other processes emanating from the cell body of a neuron, the dendrites (Figure 2). Dendrite processes are considered to be the primary site for the reception of chemical information transmitted by means of neurotransmitters released from hundreds or thousands of axon terminals impinging upon the dendrites or the soma of a single neuron. The contacts that nerve terminals make with either dendrites or the soma of a neuron are, of course, the synapses across which chemical neurotransmission takes place. Most synapses on dendrites of brain neurons occur through close approximation of nerve terminals with specialized, small processes protruding from the main shaft of a dendrite (Figure 2). These knob-like protrusions are referred to as 'dendritic spines' and represent a specialized compartment

in a neuronal dendrite. The signals initiated by Ca^{2+} entry through transmitter receptor-ion channels and back-propagating action potentials in a spine differ from those initiated in the main body of a dendrite. Therefore, integration of signals that lead to long-lasting changes in neuronal responses to incoming stimuli and to changes in gene transcription and protein synthesis is determined by signals initiated in spines as well as those in dendrites.

The narrowness of the neck of spines that connects them to the respective dendrite is thought to delay diffusion and equilibration of intra-spine Ca^{2+} with that in the dendrites. Thus, the levels of free $[\text{Ca}^{2+}]_i$ within the head of a spine are determined not only by the amount of Ca^{2+} entering the spine through receptor-activated and voltage-gated ion channels but also through the kinetics of diffusion out of the spine and the Ca-buffering capacity within the spine. Action potentials initiated in axons and invading the cell body and dendrites produce supralinear increases in free $[\text{Ca}^{2+}]_i$ in dendrites when they are coincident with synaptic activation of neurotransmitter receptor-associated Ca^{2+} channels. Supralinear increases in $[\text{Ca}^{2+}]_i$ are defined as increases that exceed the sum of net increases in free $[\text{Ca}^{2+}]_i$ brought about by the simultaneous activation of both neurotransmitter receptor channels and VGCCs. Free $[\text{Ca}^{2+}]_i$ in spines following the activation of back-propagating action potentials has been estimated to reach levels as high as $2\text{ }\mu\text{M}$. If back-propagating potentials are coupled to neurotransmitter activation of receptors that allow the influx of Ca^{2+} into neurons, such as glutamate receptors, then the levels are estimated to be more than 10-fold higher, that is, $26\text{ }\mu\text{M}$.

The coincidence of glutamate receptor-mediated and action potential-induced Ca^{2+} signals plays a crucial role in the phenomenon known as 'synaptic plasticity', that is, the

Figure 2 Diagrammatic representation of a large neuron that might be found in the neocortex or hippocampus of the brain. The structures of dendrites, dendritic spines, and axon terminals are highlighted.

long-term change in the magnitude of responses across a synapse following a series of activating stimuli delivered to a set of synapses in a neuron. Synaptic plasticity is fundamental to the processes of learning and memory and to the adaptive brain changes described above. Long-term increases in synaptic responses to a given stimulus are known as 'long-term potentiation' (LTP), and long-term decreases in such responses are known as 'long-term depression' (LTD). At the center of the molecular events that lead to synaptic plasticity are glutamate receptors, VGCCs, and intraneuronal Ca^{2+} signaling.

Glutamate Receptors in the Mammalian CNS: Structure and Function

Physiological and Pharmacological Properties of Glutamate Receptors

L-Glutamic acid is the most prevalent excitatory neurotransmitter in the vertebrate nervous system. Glutamate receptor activation is one of the stimuli for neuronal migration and synapse formation in the developing CNS, causes the elongation of neuritic processes, and enhances the survival of some neurons. However, excessive stimulation of glutamate receptors by moderately high concentrations of L-glutamate and several of its analogs, such as *N*-methyl-D-aspartate (NMDA), leads to delayed neuronal damage through the activation of apoptosis. Stimulation of glutamate receptors by even higher concentrations of L-glutamate or NMDA leads to acute toxicity through necrosis. Both the phenomena of synaptic plasticity and neuronal damage are dependent on the entry of Ca^{2+} into neurons

but they differ, of course, in the magnitude and duration of the changes in free $[\text{Ca}^{2+}]_i$.

Before proceeding with a discussion of the regulation of Ca^{2+} signaling in neurons by glutamate receptors, it is important to define the various types of glutamate receptors present in the mammalian CNS. The classification is based on pharmacological and physiological properties of neuronal glutamate receptors (Table 1). On the basis of functional characteristics, two general categories of glutamate receptors have been identified, the ion-channel-forming receptors or 'ionotropic receptors', and the receptors linked to the activation of phospholipase C (PLC) or the inhibition of adenylyl cyclases (ACs), known as the 'metabotropic receptors'. Metabotropic receptors that activate PLC also stimulate phospholipase D. Ionotropic receptors fall into three categories: those that are activated by NMDA, those that respond to kainic acid (KA), and those that are activated by α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) (Table 1). Metabotropic glutamate receptors are subdivided into groups I, II, and III based on their sensitivity to various agonists and antagonists, as well as their effects on either PLC or ACs.

KA and AMPA receptors (KARs and AMPARs) are the primary receptors for rapid excitatory transmission in the CNS. The receptor-associated ion channels activated by AMPA or KA are primarily permeable to Na^+ and K^+ . However, some AMPARs as well as some KARs form ion channels that are permeable to Ca^{2+} . AMPARs in brain neurons are activated by both AMPA and KA, but AMPA is the more potent agonist. AMPARs can be distinguished from KARs on the basis of the effects that selective allosteric modulators, the benzothiazides and AMPAkinases, and selective noncompetitive

Table 1 Classification of L-glutamate receptor subtypes found in the mammalian central nervous system

Receptor classes	Inotropic	Metabotropic		
Receptor subtype	NMDA	AMPA	Kainate	Quisqualate, L-AP4
Selective agonists (plus co-agonists)	NMDA (plus glycine or D-serine)	AMPA	Kainate	1S3RACPD, L-AP4LCCG1, LY354740, LY404039, DCG IV, ACPT III
Functional characteristics	Activation of channels for Na ⁺ , K ⁺ , and Ca ²⁺ ; slow excitation, slow desensitization	Activation of channels for Na ⁺ and K ⁺ , some Ca ²⁺ ; fast excitation, fast desensitization	Activation of channels for Na ⁺ and K ⁺ ; fast excitation, fast desensitization	Activation of PLC; activation of PLD; inhibition of AC
Other agonists	Ibotenate, L-HCA, quinolinate	(S)-ATPA, quisqualic acid, kainate, domoate, willardine	(2S, 4R)-4-methylglutamic acid, dysiherbaine, domoate, (S)-ATPA, acromelic acids A and B	Quisqualate, L-serine-O-phosphate, ibotenate, CCG
Allosteric modulators	Spermine, ifenprodil	Aniracetam, benzothiazides, CX164 (AMPAkine)	Concanavalin A (Con A)	
Competitive antagonists	2-AP5, 2-AP7, CPP, CPP-ene, CGP39653, CGS19755, biphenyl	CNQX, NBQX, DNQX	GAMS, γ-D-glutamyl-glycine	Phenylglycine analogs (3HPG, 4CPG, 4C3HPG, MCPG)
Antagonists at co-agonist or modulator sites	5,7-diCl-Kyn, HA-966, CNQX, L-689560, ifenprodil	2,3-Benzodiazepines (GYKI52466), SYM2206		
Ion channel inhibitors	PCP, MK-801, ketamine, memantine	JST, barbiturates		

AC, adenyl cyclase; ACPD, 1-aminocyclopentane-1,3-dicarboxylate; Aniracetam, 1-(4-methoxybenzoyl)-2-pyrrolidinone, L-AP4, L-2-amino-4-phosphonobutanoic acid; 2-AP5, D-2-amino-5-phosphonopentanoic acid; 2-AP7, D-2-amino-7-phosphonoheptanoic acid; (S)-ATPA, (S)-2-amino-3-(5-*tert*-butyl-3-hydroxy-4-isoxazolyl)propionic acid; CCG, 2-carboxycyclopropylglycine; CGP39653, [(±)-(E)-2-amino-7-amino-4-propyl-5-phosphonopentenoic acid; CGS19755, [(±)-2-carboxypiperidin-4-yl]methyl]-phosphonic acid; 4C3HPG, (S)-4-carboxy-3-hydroxy-phenylglycine; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; 4CPG, (S)-4-carboxy-phenylglycine; CPP, [3-[(±)-carboxypiperazin-4-yl]prop-1-yl]-phosphonic acid; CPP-ene, [3-[(±)-2-carboxypiperazin-4-yl]-propen-1-yl]-phosphonic acid; CX614, 2H,3H,6aH-pyrrolidino[2'',1''_3',2']1,3-oxazino[6',5'-5,4]benzo[*a*]1,4-dioxan-10-one; 5,7-di-Cl-Kyn, 5,7-dichlorokynurenic acid; DNQX, 6,7-dinitroquinoxaline-2,3-dione; GAMS, γ-D-glutamylamino-methylsulfonate; HA-966, 3-amino-1-hydroxy-2-pyrrolidone; 3HPG, (S)-3-hydroxy-phenylglycine; JST, Joro spider toxin; L-689,650, *trans*-2-carboxy-5,7-dichloro-4-phenylaminocarbonylamino-1,2,3,4-tetrahydroquinoline MCPG, (+)-α-methyl-4-carboxy-5,7-dichloro-4-phenylaminocarbonylamino-1,2,3,4-tetrahydroquinoline; LY354740, (1S,2S,5R,6S)-2-aminobicyclo[3.1.0]hexane-2,6-dicarboxylate monohydrate; LY404039, (−)-(1*R*,4*S*,5*S*,6*S*)-4-amino-2-sulfonylbicyclo[3.1.0]hexane-4,6-dicarboxylic acid; MCPG, (+)-α-methyl-4-carboxy-phenylglycine; MK-801, (+)-5-methyl-10,11-dihydro-5H-dibenzo[*a,d*]cyclohepten-5,10-imine; NBQX, 2,3-dihydroxy-6-nitro-7-sulphamoyl-benzo-(F)-quinoxaline; PLC, phospholipase C; SYM 2206, (±)-4-(4-aminophenyl)-1,2-dihydro-1-methyl-2-propylcarbamoyl-6,7-methylenedioxyphthalazine.

inhibitors, the 2,3-benzodiazepines, have on AMPARs but not on KARs (Table 1). Some of the selective modulators of AMPARs, the AMPAkinases, were explored as agents that might enhance memory formation in diseases that produce decrements in memory, such as the dementia of Alzheimer's disease.

NMDA receptors (NMDARs) respond to glutamate in the presence of the co-agonist glycine and such responses are slower than those following activation of either KARs or AMPARs. The slow response of NMDARs is due to the fact that they are tonically inhibited by Mg²⁺. Mg²⁺ inhibition of NMDARs is a voltage-dependent phenomenon and membrane depolarization relieves such blockade. Thus, the rapid activation of KARs and AMPARs by glutamate and the subsequent depolarization of the membrane diminishes the inhibition of NMDARs by Mg²⁺ and leads to the activation of these receptors by glutamate. In neuronal synapses on dendritic spines, both AMPA- and NMDA-sensitive receptors are proximal to each other. Back-propagating action potentials in dendrites or action potentials generated within spines and dendrites also relieve the Mg²⁺-induced inhibition of NMDAR channels.

The opening of NMDAR ion channels increases the permeability of the membrane to Na⁺, K⁺, and Ca²⁺. A unique feature of NMDARs is the requirement for the presence of nanomolar to micromolar concentrations of the co-agonist glycine in order to be fully activated (Table 1). Because of the multiplicity of sites that activate or inhibit NMDAR ion channels, antagonists for NMDARs fall under four categories (Table 1): antagonists that compete for the recognition sites of L-glutamate and NMDA (e.g., 2-AP5, 2-AP7), those that block the binding sites for the coagonist glycine (e.g., 5,7-diCl-kynurenic acid), those that inhibit the allosteric enhancement of agonist activation by the polyamines (e.g., ifenprodil), and those that inhibit the receptor-associated ion channel (e.g., dizocilpine or MK801).

Metabotropic glutamate receptors (mGluRs) are localized primarily in what is known as the perisynaptic region of dendritic spines, that is, not within the synapse as AMPARs, KARs, or NMDARs do. These receptors are apparently not activated by the release of neurotransmitter glutamate following single-action potentials but rather following repeated, high-frequency stimulation of axons and their nerve endings. Of particular interest with regard to Ca²⁺ signaling in neurons is the fact

that group I mGluRs produce two types of neuronal depolarization, a rapid, transient depolarization related to the release of Ca^{2+} from intracellular stores and a prolonged and larger depolarization resulting from activation of transient receptor potential Ca^{2+} channels. The release of Ca^{2+} from intracellular stores is the result of inositol-1,4,5-triphosphate (InsP_3) formation and the activation of InsP_3 receptor-ion channels on endoplasmic reticulum membranes. This transient elevation in intracellular Ca^{2+} causes propagating increases in free $[\text{Ca}^{2+}]_i$ and elicits changes in the activity of CNS neurons that are dependent on protein synthesis, that is, it has some of the characteristics of long-term changes associated with synaptic plasticity. In addition, these Ca^{2+} transients can produce supralinear increases in free $[\text{Ca}^{2+}]_i$ in dendrites and spines

of CNS neurons if they occur at the same time as back-propagating action potentials.

Molecular Structure of Glutamate Receptors

The cloning of the complementary DNAs (cDNAs) for glutamate receptors has revealed a great complexity in the structure of these receptors (Table 2 and Figures 3 and 4). The size of all glutamate receptor proteins represented by the cDNAs for GluR1, NMDAR1, mGluR1, and their homologs (95–163 kDa) is larger than that for other neurotransmitter receptor proteins, both ion-channel-forming receptors and G-protein-coupled receptors (Table 2 and Figures 3 and 4). Based on the amino acid sequence of the proteins for the ionotropic receptors

Table 2 Characteristics of the cloned glutamate receptors, including some putative receptors with ligand-binding characteristics similar to glutamate receptors, from mammalian and amphibian brain

Subunits	Receptor type	Protein size (kDa)	Protein assembly	Functional properties
GluR1	AMPA (KA)	99.8	GluR1–4; most native receptors contain GluR 2	Glutamate, AMPA, KA-activated channels; low Ca^{2+} permeability
GluR2		96.4		
GluR3		98		
GluR4		101		
GluK1	KA	102.8	GluK1 with GluK2–GluK5	Glutamate and KA-activated channels; rapidly desensitizing
GluK2		93.9		
GluK3		100		
GluK4		105		
GluK5		109		
KBP-chick	KA binding	51.8	Single subunit	No channel function
KBP-frog		52.5		
$\delta 1$	Orphan receptor	110.4	Unknown	No channel function
$\delta 2$		113.2		
NMDAR1a	NMDA	103.5	With NMDAR2 or NMDAR3	NMDA-activated channels; glycine a co-agonist high Ca^{2+} permeability, MK-801 and ketamine block; voltage-dependent Mg^{2+} block
NMDAR2A		163.3	With NMDAR1 and other NMDAR2	
NMDAR2B		162.9	With NMDAR1 and other NMDAR2	
NMDAR2C		133.5	With NMDAR1 and other NMDAR2	
NMDAR2D		140.6	With NMDAR1 and other NMDAR2	
NMDAR3A		124.5	With NMDAR1	Glycine-activated excitatory responses; Na^+ , K^+ channels; not permeable to Ca^{2+} ; no Mg^{2+} blockade
NMDAR3B		109	With NMDAR1	Same as for NR-3A
GBP	NMDAR-like complex	57	With GlyBP, TCP-BP, CPP-BP,	Reconstituted complex forms NMDA-activated ion channels; glycine a co-agonist, MK-801 and ketamine inhibit; low sensitivity to Mg^{2+}
GlyBP	NMDAR-like complex	52.7	With GBP, TCP-BP, CPP-BP	
CPP-BP	NMDAR-like complex	78.3	With GBP, GlyBP, TCP-BP	
TCP-BP	NMDAR-like complex	8.9 & 9.5, Bicistronic	With GBP, GlyBP, CPP-BP	
mGluR1a	Metabotropic GluRs	133.2	Single protein receptor; coupled to G proteins	mGluR1, mGluR5: activation of PLC and PLD
mGluR2		95.8		mGluR2, 3, 4, 6, 7, 8: inhibition of adenylyl cyclases
mGluR3		99		
mGluR4a		101.8		
mGluR5a		128.3		
mGluR6		95.1		
mGluR7		102.2		
mGluR8		97.5		

Figure 3 Linear representation of the structure of the cloned ionotropic glutamate-receptor proteins, including two orphan receptors. Shown are the NMDA, AMPA, and KA receptor proteins, as well as some of the orphan receptor proteins, and the variant forms of NMDAR1 that result from alternative RNA splicing. Such alternative splicing leads to the addition or deletion of amino acid residues at either the amino (NH₂) or carboxyl (COOH) terminal of the protein. All proteins are shown to contain three hydrophobic domains (designated M1–M3) and the P loop at the pore region (black boxes). For the proteins GluR1–4, the presence of the flip and flop splice variants in the region between M2 and M3 is indicated by boxes above the diagram of each receptor protein. Modified from Michaelis EK (1998) Molecular biology of glutamate receptors in the central nervous system and their role in excitotoxicity, oxidative stress and aging. *Progress in Neurobiology* 54: 369–415.

Figure 4 Linear representation of the structure of the cloned metabotropic glutamate receptor proteins mGluR1–8, including several splice variants. The seven hydrophobic domains considered as the likely transmembrane regions of the proteins are designated as M1–M7 and are shown as black boxes. Modified from Michaelis EK (1998) Molecular biology of glutamate receptors in the central nervous system and their role in excitotoxicity, oxidative stress and aging. *Progress in Neurobiology* 54: 369–415.

and the relative hydrophobicity of various domains in the proteins, it was predicted that each ionotropic receptor protein cloned had a large extracellular amino-terminal region and three transmembrane domains, M1–M3. Ionotropic glutamate receptors are macromolecular complexes composed of four subunits. Identification of the agonist-binding sites of the GluR and GluK subunits was initially achieved by analysis of chimeras made of GluR3, an AMPAR protein, and GluK2, a KAR protein. The last 150 amino acids before the M1 domain and the amino acids right after M2 in the extracellular loop between M2 and M3 are crucial in determining ligand-binding selectivity of these proteins. Site-specific mutagenesis and crystallographic studies of the extracellular domain have led to the characterization of the agonist-binding site as one that is formed in a bi-lobed manner by the S1 and S2 domains (Figure 5). The S1 and S2 domains are also the sites of binding of allosteric modulators that prevent receptor desensitization, for example, the binding site for cyclothiazide to AMPARs.

On the intracellular side of the plasma membrane, the domain between M1 and M2 forms a loop at the opening of the ion channel but does not traverse the membrane bilayer. This is the P domain (Figure 5). Structurally, the ion-channel-forming region of KARs, AMPARs, and NMDARs exhibits high homology to voltage-gated K⁺ channels, especially the P loop at the opening of the ion channel. Single amino acid substitutions in the P loop affect the permeability of the channel to Ca²⁺ dramatically.

AMPA Receptor Genes and Protein Structure

With regard to the structure of native AMPARs, homomers of any of the proteins GluR1–4 form ion channels that are activated by both AMPA and kainate and exhibit the characteristics of neuronal AMPARs. GluR1–4 receptor proteins (*Gria1–4* corresponding genes) are expressed broadly throughout the CNS. Forms of AMPARs that are derived from alternatively spliced exonic sequences in the respective messenger RNAs (mRNAs) are also expressed in the CNS (Figure 3). With regard to Ca²⁺ permeability of the ion channels associated with AMPARs, the key subunit is the GluR2 subunit. When this subunit is present in a receptor complex, then the AMPARs exhibit a linear relationship between voltage applied to the membrane and the current conducted through the receptor channels and have very low permeability to Ca²⁺, that is, they resemble most native AMPA receptors of CNS neurons. Homomeric complexes made of the GluR1, GluR3, or GluR4 proteins form channels that are permeable to Ca²⁺. The restriction of Ca²⁺ permeability imparted to receptor complexes by the presence of the GluR2 subunit is dependent on a crucial Arg586 (R586) in the P loop of this subunit. The corresponding residue in GluR1 is Gln582 (Q582) (Figure 5), and mutation of this Gln residue to Arg abolishes the Ca²⁺ permeability of channels formed by homomeric expression of the GluR1 protein. GluR3 and GluR4 also have Gln residues in the P loop.

The Arg residue in the P loop of GluR2 is the result of RNA editing. The gene codon for the amino acid at this position is cytosine–adenine–guanine (CAG) for Gln, not cytosine–guanine–guanine (CGG) for Arg. The pre-messenger

Figure 5 A representation of the distribution of different domains of the AMPA receptor (GluR proteins) in the neuronal membrane (a) and an enlarged view of the formation of a hairpin loop at the inner opening of the ion channel by the P loop. The formation of a glutamate-binding site by the two lobes of the protein projecting to the extracellular environment, domains S1 and S2, is also shown. Reproduced from Michaelis E (1998) Molecular biology of glutamate receptors in the central nervous system and their role in excitotoxicity, oxidative stress and aging. *Progress in Neurobiology* 54: 369–415.

RNAs (pre-mRNAs) are edited by an adenosine deaminase whose activity depends on the presence of the double-stranded RNA (dsRNA) structure between exon 11 and intron 11 of the GluR2 pre-mRNA. The adenosine in the CAG codon is deaminated to inosine, thus forming the cytosine-inosine-guanine (CIG) codon for Arg. This dsRNA deaminase is expressed in brain and other tissues and edits with very high efficiency (~90%) and selectivity GluR2 pre-mRNA. In the disease amyotrophic lateral sclerosis, editing of GluR2 is significantly less complete and leads to the expression of AMPARs in spinal neurons that are highly permeable to Ca^{2+} . This increased permeability to Ca^{2+} may cause neuronal death during the lifespan.

KA Receptor Genes and Protein Structure

Homomers or heteromers of GluK1, GluK2, or GluK3 (*Grik1–3* corresponding genes) form channels that resemble KARs in brain neurons. On the other hand, homomers of GluK4 or GluK5 (*Grik4–5* corresponding genes) fail to form channels unless they are co-expressed with GluK1–3. The channels formed by co-expression of GluK4 or GluK5 with one of the other KAR subunits leads to channel formation with differential pharmacological sensitivities and channel activation and desensitization kinetics. The expression of the KAR-like proteins $\delta 1$ and $\delta 2$, either as homomeric or heteromeric complexes, does not lead to ion channel formation. Therefore, these two genes are designated as orphan receptors. Based on these observations, GluK1–5 are considered to be the true

subunits of neuronal KARs. Different sets of neurons in the brain express these KAR receptor proteins and some of them, for example, those in the CA3 field of the hippocampus, are some of the most vulnerable brain neurons to KA-induced neurotoxicity (neurotoxic KARs) as well as to seizure-induced neuronal damage.

The RNA for GluK1 and GluK2 is also edited leading to a Gln to Arg change in the P loop. However, the efficiency of editing (35% and 75%, respectively) is lower than that observed for GluR2. For the GluK2 receptor protein, the permeability of the channel for Ca^{2+} is controlled not only by the editing of the Gln residue in the P loop but also by the editing of two other residues in the M1 domain of the protein.

NMDA Receptor Genes and Protein Structure

Expression of the NMDAR2A–D (*Grin2a–d* corresponding genes) subunits by themselves does not lead to the formation of functional NMDARs, but the co-expression of the NMDAR2 subunits together with NMDAR1 (*Grin1* corresponding gene) leads to the formation of ion channels that have conductances very similar to those of NMDA receptors in neurons. In the NMDAR1 protein, the amino acid present in the corresponding position as Arg586 in GluR2 is Asn598. The channels formed by these subunits of NMDARs are highly permeable to Ca^{2+} . Finally, each of the combinations of NMDAR1 and one of the NMDAR2 subunits exhibit different degrees of sensitivity to

the co-agonist glycine, the competitive antagonist 2-AP5, and the channel inhibitor Mg^{2+} .

The expression of NMDAR3A, B (*Grin3a,b* corresponding genes) together with NMDAR1 and NMDAR2 subunits leads to receptor-ion channels activated by glycine. These channels have lower conductance levels than those of NMDAR1/NMDAR2 receptor-ion channels, low Ca^{2+} permeability, and insensitivity to Mg^{2+} -induced channel block.

The glycine-binding site of NMDARs is in the NMDAR1 subunit and is formed by domains equivalent to the S1 and S2 domains of GluR1–4. The primary glutamate/NMDA-binding site of NMDARs is localized on the corresponding extracellular domains of the NMDAR2 subunits. Each NMDAR1 and NMDAR2 subunit pair forms a dimer through interactions at the S1–S2 domains. In addition to the seven isoforms of NMDARs, there are eight splice variant forms of NMDAR1 (NMDAR1a–h, [Figure 3](#)). These splice variant forms exhibit clearly distinguishable sensitivities to agonists, antagonists, Zn^{2+} , and polyamines. Thus, a wide array of receptor complexes with differing affinities for ligands may be expressed in neurons through different combinations of the NMDAR1/R2 subunits, as well as the NMDAR1 splice variants. Differential expression and localization of the NMDAR1 subunits in various brain regions or even within a single neuron, for example, cell body versus dendrites, could influence the responses of neurons to synaptically released L-glutamic acid.

Most synaptic NMDARs are formed by a combination of NMDAR1/R2A/R2B. Localization of the NMDAR proteins in synaptic regions is determined by the carboxyl-terminal region of the NMDAR1 and NMDAR2 subunits (NMDAR2A and 2B). Mice lacking one of the NMDAR2 subunits (NMDAR2A) have diminished NMDA receptor channel activity and a reduction in the process of induction of LTP in CNS neurons.

Neuronal toxicity produced by NMDA also depends on the specific combination of subunits that form the receptors in neurons. Cells of the human embryonic kidney cell line 293, for example, die when they are transiently transfected with the NMDAR1 and NMDAR2 subunits and such toxicity is greatest when NMDAR1 and NMDAR2A are co-expressed, less if NMDAR2B is co-expressed with NMDAR1, and it is not apparent when the NMDAR2C subunit is co-expressed with NMDAR1.

mGluR Genes and Proteins

Eight forms of mGluR genes have been identified ([Figure 4](#)). Group I are the mGluR1 and mGluR5, group II are the mGluR2 and mGluR3, and group III are mGluR4 and mGluR6–8. The activation of PLC by mGluR1 and 5 appears to involve transduction of the signal through coupling of the receptor proteins with either the Gi–Go family of guanosine triphosphate (GTP)-activated proteins (G proteins) or the Gq family. All of the group II and III mGluR proteins appear to be coupled to the Gi–Go family of G proteins. All mGluR proteins have a large extracellular amino-terminal domain, which contains a region that is homologous to bacterial periplasmic-binding proteins. It is likely that the glutamate-binding sites on mGluRs are within this extracellular domain. Insertions or deletions due to alternative mRNA splicing are confined to the carboxyl-terminal region and do not disrupt the amino-terminal domain of mGluRs.

Glutamate Receptors, Ca^{2+} -Signaling, and Synaptic Plasticity

Coincidence of action potentials in spines and dendrites with synaptic activation of glutamate receptors, primarily NMDARs, can enhance Ca^{2+} entry into neurons and produce long-lasting changes in synaptic activity. The timing of the two events, action potentials, and synaptic activation of receptor-induced Ca^{2+} influx, appears to be crucial. If receptors are activated after an action potential invades dendrites, it produces LTD. If it precedes or is coincident with the action potential it produces LTP. Activation of Ca^{2+} influx seems to be a key event in the expression of synaptic plasticity and neuronal adaptation but such increases in free $[Ca^{2+}]_i$ frequently work in a cooperative manner with other signaling events, such as the formation of cyclic adenosine monophosphate (AMP) (cAMP) and the activation of cAMP-dependent protein kinase A (PKA). For example, the establishment of LTP in some neurons is strengthened by the concurrent activation of neurotransmitter receptors that activate ACs, such as, dopamine, muscarinic acetylcholine, and β -adrenergic receptors.

The entry of Ca^{2+} into neurons following glutamate receptor activation, especially activation of NMDA receptors, or the opening of VGCCs leads to altered gene transcription, mRNA splicing, mRNA translation, and protein synthesis. These effects are, to a substantial degree, dependent on the stimulation of several kinases, including Ca^{2+} /calmodulin (CaM)-dependent kinases (CaMK), protein kinase C (PKC), extracellular signal-regulated kinase or mitogen-activated kinase (ERK or MAPK), MAPK-ERK kinase (MEK), stress-activated protein kinase, aurora kinase, and protein tyrosine kinases such as proline-rich tyrosine kinase and src kinase ([Figure 6](#)). However, not all types of Ca^{2+} influx into a cell lead to the same level of activation of gene transcription, even when the levels of $[Ca^{2+}]_i$ achieved are the same. There is clear compartmentalization of Ca^{2+} arriving at synaptic junctions as opposed to those received following generalized depolarization of a neuron. Ca^{2+} that enters following activation of either a receptor-ion channel or a VGCC apparently remains very close to the internal mouth of the channel (~ 100 nM radius). Even if all other free Ca^{2+} in dendrites and cell bodies of neurons is chelated, the localized Ca^{2+} near ion channels still function as an intracellular signal. Most likely readout of Ca^{2+} signaling is that of changes in the frequency of transient Ca^{2+} elevations and the most likely sensor of such frequency modulations is CaMKII. It is important to note that the mRNA for CaMKII α is selectively transported to the dendritic region of neurons and that activation of NMDARs leads to polyadenylation of CaMKII α mRNA and initiation of its translation through a process dependent on aurora kinase stimulation.

Stimulation of protein phosphorylation is pivotal in the activation of signal transduction cascades that leads to altered transcriptional regulation ([Figure 6](#)). A transcription factor that is sensitive to activation by several incoming stimuli and that regulates the expression of as many as 100 other genes, is the cAMP response element (CRE)-binding protein (CREB). A key gene whose transcription is regulated by CREB is that for brain-derived nerve growth factor (BDNF), a gene that is known to influence the establishment of LTP. CREB activation is dependent on phosphorylation of crucial Ser residues.

Figure 6 Regulation of transcription in neurons by Ca^{2+} following activation of NMDARs or VGCCs, and the interaction with pathways of gene transcription regulation following stimulation of G-protein-coupled receptors. Shown is the Ca^{2+} -induced and cAMP or diacylglycerol (DAG)-induced stimulation of kinases that phosphorylate CREB and cause activation of gene transcription. Also shown is the activation by Ca^{2+} and CaM of the protein phosphatase 3 (PP3) or calcineurin and the subsequent dephosphorylation of NFATc, the translocation of NFATc into the nucleus and the regulation of gene transcription in neurons. More details are presented in the text. CBP, CREB-binding protein.

CaMKIV, when directly activated by Ca^{2+} and CaM in the nucleus, phosphorylates CREB. But Ca^{2+} entering neurons through NMDA and VGCCs also leads to CREB phosphorylation through the activation of MAPK/ERK and RSK2 kinases (Figure 6). Activation of the small GTPase Rap 1 follows binding of the Ca^{2+} -CaM complex to a guanine-nucleotide exchange factor, Ras guanine-nucleotide-releasing factor (Ras-GRF1, Figure 6). The same cascade of kinases can also be activated by cAMP and PKA and by diacylglycerol (DAG) and PKC, thus leading to the potential strengthening of signal transduction by Ca^{2+} following coincident activation of receptors coupled to ACs or those coupled to PLC (Figure 6).

Ca^{2+} entry following NMDAR or VGCC activation also leads to the stimulation of the Ca^{2+} plus calmodulin-activated phosphatase PP3 (calcineurin) and, as a consequence of that, to the activation of the transcription factors nuclear factor of activated T cells (NFATc) and myocyte enhancement factor 2a. Activation of these two transcription factors is important in determining neuronal survival, axon and dendrite growth, synapse formation, and overall brain development. The transcription of some 34 genes is thought to be either up- or downregulated by NFATc in neurons. A prominent gene whose transcription is upregulated is the InsP_3 receptor-ion channel (Figure 6).

The activation of kinases following stimulation of glutamate receptors is thought to be a key step in the formation of LTP and memory formation, whereas the activation of calcineurin following weak stimulation of glutamate receptors is thought to cause primarily LTD. It is also noteworthy that phosphorylation of NMDARs by PKC, CaMKII α , or protein tyrosine kinases leads to increases in the response to agonists whereas activation of calcineurin or protein tyrosine phosphatases diminishes NMDAR responses. Given the importance of

NMDARs in synaptic plasticity and neuronal adaptation, it is not surprising to find such complex orchestration of protein modifications by kinases and phosphatases and of the consequent alterations in the activity of the receptors.

Glutamate Receptors, Ca^{2+} , and Neurodegeneration

Excessive activation of glutamate receptors leads to neuronal degeneration in the mammalian brain, such as that occurring during ischemia, anoxia, hypoglycemia, epileptic seizures, and chronic neurodegenerative diseases, for example, Alzheimer's disease. The entry of Ca^{2+} into neurons increases the activity of the calmodulin-activated form of nitric oxide synthase. Activation of this enzyme leads to the generation of intracellular nitric oxide radical ($\text{NO}^\bullet$) which, together with superoxide anion ($\text{O}_2^{\bullet-}$), forms peroxynitrite and leads to delayed neurotoxicity. Also, Ca^{2+} entry after activation of populations of nonsynaptic NMDA receptors is the primary contributor to alterations in mitochondrial Ca^{2+} handling and the initiation of neuronal apoptosis. The entry of Ca^{2+} through NMDA receptors also leads to the activation of proteases, such as Ca^{2+} -activated calpain, and enhanced proteolytic activity. Finally, activation of calcineurin and NFATc by Ca^{2+} entry into neurons has been shown to play an important role in Alzheimer's disease-related neuropathology.

Ligand-Operated Membrane Channels: GABA

F Minier, François-Rabelais University, Tours, France

E Sigel, University of Bern, Bern, Switzerland

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chloride equilibrium potential Membrane potential at which opening of chloride-ion-selective channel mediates no net ion flux due to the concentration gradient of the corresponding ion.

Conservative substitution Replacement of an amino acid residue by a residue with similar chemical properties.

Heterologous expression Genetic information in the form of complementary DNA (cDNA) or complementary RNA

(cRNA) is introduced into a foreign cell where the encoded protein is synthesized.

Hydrophobicity analysis The amino acid residue sequence predicted by the coding cDNA is scanned for the average hydrophobicity of a window of about 20 succeeding amino acid residues. A longer hydrophobic stretch is indicative of a transmembrane sequence in the protein.

Voltage clamp Imposition of a desired membrane potential on a cell using electrophysiological techniques.

Handling of the Neurotransmitter GABA: Biosynthesis, Transport, and Degradation

γ -Aminobutyric acid (GABA) is synthesized from glutamate in the cytosol of GABAergic neurons by two types of glutamic acid decarboxylase (GAD), namely, GAD65 and GAD67, according to their molecular weights (Figure 1). GAD65 is important for the local control of GABA synthesis at the synaptic sites, whereas GAD67, more widely distributed in the cell, is responsible for maintaining GABA baseline levels. After biosynthesis, GABA is loaded into synaptic vesicles by a vesicular transporter named 'vesicular inhibitory amino acid transporter (VIAAT)' or 'vesicular GABA transporter (VGAT)'. This transporter is predicted to be a 10-transmembrane domain protein and belonging to a superfamily of H^+ -neurotransmitter transporters. Presynaptic membrane depolarization triggers release of GABA into the synaptic cleft. After the activation of $GABA_A$ and $GABA_B$ receptors, GABA is taken up in surrounding neuronal and glial cells by high-affinity GABA transporters (GATs). This re-uptake contributes to the termination and modulation of GABA neuronal transmission. GATs belong to a superfamily of Na^+/Cl^- -dependent neurotransmitter transporters. Four GATs have been cloned: GAT-1, GAT-2, GAT-3, and betaine GABA transporter (BGT-1). They are 12-transmembrane domain proteins with both intracellular N and C termini, and an extracellular loop between transmembrane domains 3 and 4. Each of these transporters displays specific features: GAT-1 seems to be highly expressed throughout the brain at a neuronal presynaptic localization, while GAT-2 is mainly extra-parenchymal and found in the meninges. GAT-3 displays a similar macroscopic distribution as GAT-1. It is expressed in both presynaptic neurons and astrocytes. BGT-1 is weakly expressed throughout the brain in postsynaptic neuronal cells. The GABA degradation pathway, called 'GABA shunt', is one of the energy synthetic pathways in the brain. This pathway is composed of consecutive actions of three enzymes. The mitochondrial enzyme GABA-transaminase (GABA-T) catabolizes GABA to succinic semialdehyde (SSA). Then, SSA is converted either to succinic acid (a substrate for the Krebs cycle) by succinic semialdehyde dehydrogenase (SSADH)

or to γ -hydroxybutyrate (GHB) by succinic semialdehyde reductase (SSAR). All these pathways are summarized in Figure 1.

Early $GABA_A$ Receptor Biochemistry

Indirect evidence suggested a close relation of the $GABA_A$ receptor and the benzodiazepine-binding site. The benzodiazepine drugs are widely used for their sedative, anxiolytic, muscle relaxant, and anticonvulsant action. Affinity chromatography directed at the benzodiazepine-binding site led to the isolation of a pure protein complex with binding properties expected for the $GABA_A$ receptor and for its chloride pore. This demonstrated the presence of benzodiazepine-binding sites within the $GABA_A$ receptor. The subunits of the complex had a molecular mass of 49–58 kDa and the entire complex of ~250 kDa. Later, it became clear that five subunits surround the central ion pore.

Molecular Biology of the $GABA_A$ Receptor

Two $GABA_A$ receptor subunits were initially cloned. Hydrophobicity analysis indicated the presence of four membrane-spanning regions (Figure 2(b)). The second transmembrane segment of each of the five subunits contributes to the ion pore. Initial cloning was quickly followed by cloning of closely related subunits α_{1-6} , β_{1-3} , γ_{1-3} , δ , ϵ , θ , and π . At the genomic level, these subunits are organized on chromosomes in clusters, raising the possibility of a cluster-specific regulation of expression (Table 1). If the degree of amino acid sequence identity was >80%, subunits were grouped under the same Greek letter, if it was lower a new Greek letter was used. In both cases, subunits share predicted topology and there are many conservative substitutions of amino acid residues. With a sequence identity of ~20%, the subunits are also homologous to subunits of the other members of the same channel family including the nicotinic acetylcholine receptor, the glycine receptor, and the 5-hydroxytryptamine 3 (5HT₃) receptor.

Figure 1 GABAergic synapse and main GABA metabolic pathways. GABA is synthesized from glutamate by the enzyme glutamate decarboxylase (GAD). Glutamate itself is synthesized from α -ketoglutarate (α -ketoglut.). The end of its action is determined by the GABA transporters of the GAT type or BGT-1 (for betaine/GABA transporter) and intracellular degradation by GABA transaminase (GABA-T) to succinic semialdehyde (SSA) and subsequently by succinic semialdehyde reductase (SSAR) to γ -hydroxybutyrate (GHB) or by succinic semialdehyde dehydrogenase (SSADH) to succinate, which is part of the Krebs cycle. Succinate in turn is converted to α -ketoglutarate.

Thus, 16 subunits of the GABA_A receptor are available and frequently many of them are coexpressed in the same cell. On the other hand, only five subunits can be accommodated in a single channel. Today, it is not known how many different GABA_A receptors exist and what their subunit composition is, but this diversity of subunits indicates that there may exist a large variety of GABA_A receptors. The major adult GABA_A receptor isoform is likely to be composed of $2\alpha_1$, $2\beta_2$, and $1\gamma_2$ subunits. Attempts to demonstrate coassembly of different subunit isoforms into a common pentamer have included immunoprecipitation and subsequent analysis of the precipitate, a type of approach heavily relying on excellent quality antibodies.

Physiological Function

In Situ Studies

GABA induces a conformational change in the receptor protein, such as to allow chloride ion flux. This ion flux may be measured as current flowing through the membrane by using electrophysiological techniques. Current amplitude depends on the concentration of GABA applied. While it is thought that the synaptic cleft is briefly flooded with GABA during activation of the synapse and, as a consequence, receptors on the postsynaptic membrane are maximally activated, a graded response may be obtained in receptors localized extrasynaptically and in

artificial systems. As a consequence of chloride channel opening, the membrane potential of the corresponding neuron will tend to move toward the chloride equilibrium potential which is about -75 mV in mature neurons. In case the GABA_A receptor has a postsynaptic localization, this opening of chloride ion channels following neurotransmitter release from the presynaptic neuron will be brief (~ 50 ms) and transient. These receptors mediate fast synaptic inhibition. GABA will then partially diffuse out of the synaptic cleft and trigger opening of extrasynaptic receptors. In this case, opening will be prolonged and a tonic inhibition will result.

Modulation

Benzodiazepines, neurosteroids, and barbiturates modulate the ion flux, while picrotoxinin inhibits it by blocking the pore and bicuculline, a plant alkaloid, acts at the GABA site as competitive inhibitor. Modulation by benzodiazepines will be briefly summarized here. On their own, classical benzodiazepines (such as diazepam) do not induce opening of the ion pore. If they are coapplied with the agonist GABA, they lead to an increase in the current (**Figure 3**) through an allosteric increase of the apparent affinity of the receptor for GABA to elicit channel opening. At the single channel level, this stimulation is evident as an increase in channel open frequency, at least when GABA is applied at submaximal

Figure 2 (a) The GABA_A receptor is built of five membrane protein subunits that surround a central chloride selective channel. Opening of this ion channel is caused by a conformational change in the protein occurring as a consequence of the binding of the channel agonist GABA. Various drugs (benzodiazepines and neurosteroids) modify channel opening and picROTOXIN blocks the pore. (b) Topology of a subunit characterized by a large N-terminal extracellular domain carrying the drug-binding sites. The second transmembrane domain lines the ion channel. The large loop between transmembrane segments 3 and 4 carries sites for posttranslational modification (phosphorylation).

Table 1 At the genomic level, GABA_A receptor subunits are organized into gene clusters whose chromosomal location is given for the human species

Subunits	Locus
δ	1p
$\alpha_2, \alpha_4, \beta_1, \gamma_1$	4p14–p12
$\alpha_1, \alpha_6, \beta_2, \gamma_2, \pi$	5q31–q35
$\alpha_5, \beta_3, \gamma_3$	15q11–q13
$\alpha_3, \epsilon, \theta$	Xq28

It is a major challenge for basic research to bring order in this subunit chaos, to establish the subunit composition of GABA_A receptors really existing *in vivo*, and, most importantly, to find drugs that selectively modulate their function.

concentrations. These benzodiazepines are therefore called ‘positive allosteric modulators’. There exist competitive antagonists (such as Ro 15–1788) and negative allosteric modulators as illustrated here with the β -carbolines (Figure 3). The picture

Figure 3 (a) Superfusion of a cell expressing GABA_A receptors with GABA induces an ion current that is measured using the two-electrode voltage-clamp technique. Superfusion of the same cell with the positive-allosteric modulator diazepam (prototype of benzodiazepines) does not elicit any current response while combined application of GABA and diazepam elicits a much bigger response than GABA alone. (b) Analogous experiments with the benzodiazepine antagonist Ro 15–1788, which binds with high affinity to the benzodiazepine-binding site but fails to alter the current responses. (c) Analogous experiment with a negative allosteric modulator of the β -carboline class, leading to a decrease in the current response.

is complicated by the fact that there exists a continuum of partial positive and negative allosteric modulators.

In Vitro Studies

Heterologous expression has been used to identify subunit isoforms that can form together a functional pentamer. This has been possible in cases where a certain subunit isoform confers to the receptor distinct functional properties. Such studies established, for example, that the combination of α - and β -subunits produces GABA-gated currents, but coexpression of a γ -subunit is required for benzodiazepine sensitivity of the expressed receptors. It has also been possible to exclude many theoretically possible subunit combinations.

Transgenic Mice

Transgenic mice either lacking a subunit isoform or carrying a diazepam-insensitive subunit isoform have been used to assign function or drug effects to an individual subunit isoform. Such studies have shown that α_1 contributes to the sedative effects, α_2 and α_3 to the anxiolysis induced by diazepam, and that α_5 is involved in memory functions.

Figure 4 Subunit arrangement of the major isoform of the GABA_A receptor showing the arrangement of subunits around the central ion channel as seen from the synaptic cleft. The benzodiazepine-binding site (D) is located at the $\alpha_1\gamma_2$ -subunit interface in a homologous position to the two GABA (G)-binding sites located at $\beta_2\alpha_1$ -subunit interfaces.

Agonist- and Drug-Binding Sites

The following techniques have contributed to the description of amino acid residues involved in the interaction with the channel agonist GABA, its competitive antagonists, for ligands of the benzodiazepine-binding site, and for picrotoxinin: photoaffinity labeling, point mutation combined with either ligand-binding studies or functional characterization, cysteine point mutant ligand accessibility as determined by covalent modification by a chemically modified, cysteine-reactive ligand, and its protection by the corresponding ligand. The binding sites of other drugs such as barbiturates are still characterized to a lesser extent. Amino acid residues located in the N-terminal extracellular part of both the β_2 - and α_1 -subunits are taking part in the formation of the agonist-binding site, while residues on the α_1 - and γ_2 -subunits are taking part in the formation of the benzodiazepine-binding site in the major isoform of the GABA_A receptor. Both binding sites are thus located at subunit interfaces. Interestingly, both sites show a high degree of homology to each other, but only at the structural level and not at the functional level, as GABA can open the channel while benzodiazepines cannot. It should be noted that the benzodiazepine-binding site accepts not only benzodiazepines as allosteric modulators, but also some drugs with β -carboline, imidazopyridine, triazolopyridazine, and cyclopyrrolone structures.

Recently, an acetylcholine-binding protein homologous to the N-terminal extracellular portion of the nicotinic acetylcholine receptor has been crystallized. The GABA_A receptor shares structural and, to a small extent, sequence homology with the crystallized protein. The crystallized protein in its native state is able to bind acetylcholine, and a cavity binding this ligand has been identified. As the agonist-binding sites of the ligand-gated ion channel family have been conserved and as the binding pocket for benzodiazepines is homologous to the agonist site, this cavity must then be homologous to the binding pocket for benzodiazepines. The binding site is located in a cleft between

two subunits. This fits very well with the data obtained using classical methods, which indicated importance of the corresponding amino acid residues on α_1 and γ_2 that participate in the formation of the binding site. Thus, in $\alpha_1\beta_2\gamma_2$ GABA_A receptors, the binding pocket for benzodiazepines is located in a subunit cleft between α_1 - and γ_2 -subunits in a position homologous to the agonist-binding site for GABA that is located between β_2 - and α_1 -subunits (Figure 4).

Subtly Altered Receptor Subunits Cause Diseases

In several different cases, human point mutations in the γ_2 -subunit have been shown to occur in families with inherited forms of epilepsy. In both cases, not only the mutation has been tightly linked to the disease but also chloride ion flux is decreased, leading to a reduced state of neuronal inhibition. It can be anticipated for the future that many other diseases will be linked to isoforms of this important receptor. The GABA_A receptor has especially been implicated in pathological anxiety, insomnia, and epilepsy.

Architecture

The structure of the acetylcholine-binding protein has given an idea of how the extracellular domain of the GABA_A receptor could look like. The availability of a crystal structure of a protein homologous to the binding domain has also allowed establishment of the steric orientation of the subunits. From the study of covalently linked subunits, it has been concluded that the arrangement of subunits of the major GABA_A receptor isoform is $\beta\alpha\gamma\beta\alpha$. However, this still allows for a clockwise or counterclockwise arrangement. Figure 4 shows the correct arrangement as viewed from the synaptic cleft taking into account the information provided by the crystallization study.

Light-Harvesting Complex I and II: Pigments and Proteins

S Jansson, University of Umeå, Umeå, Sweden

© 2013 Elsevier Inc. All rights reserved.

Glossary

Light-harvesting complex I (LHC I) The light-harvesting system containing proteins and pigments, associated with PS I.

Light-harvesting complex II (LHC II) The light-harvesting system containing proteins and pigments, associated with PS II.

Xanthophyll cycle The light-dependent conversions of the three xanthophylls – violaxanthin, antheraxanthin, and zeaxanthin; it plays a significant role in photoprotection.

Heterogeneity of Light-Harvesting Systems

Different taxa of photosynthetic organisms have organized light-harvesting systems in different ways, that is, have rather different light-harvesting proteins and pigments. In fact, phylogenetic grouping of photosynthetic organisms is often based on their light-harvesting pigments. Green sulfur bacteria get their color from bacteriochlorophyll *c*, *d*, or *e* in the chlorosome complex; red algae from phycoerythrin; and cyanobacteria from phycocyanin in their phycobilisomes. Green algae and higher plants have chlorophyll (chl) *a* and *b* in their light-harvesting complex I (LHC I) and LHC II. The antenna proteins from these phylogenetic group complexes share no sequence homology and light-harvesting systems are therefore likely to have evolved several times in contrast to photosynthetic reaction centers that seem to have only evolved once. The LHC systems of all higher plants (angiosperms and gymnosperms) as well as ferns, mosses, and green algae are, however, homologous structures and have a lot in common and these antenna systems will be described using examples from angiosperms, whose antennas are best studied.

The Higher Plant Light-Harvesting Antenna

The higher plant LHC proteins bind, via noncovalent bonds, the antenna pigment chl *a*, chl *b*, and a set of xanthophylls (carotenoids). The LHC proteins of most plants bind the same set of xanthophylls, lutein, violaxanthin (that can get photoconverted), and neoxanthin, although some plant species may contain unusual light-harvesting carotenoids. Since the excited state of chl *b* has a higher energy as compared to that of chl *a*, the preferred energy transfer path is from chl *b* to chl *a*. This energy transfer is supposed to take place through the Förster mechanisms, that is, excitation energy can jump between electrons in neighboring pigment molecules by a dipole–dipole mechanism. The chl molecules bound to the LHC proteins are, however, in different chemical environments and have thus different excitation energies, so some chl *a* molecules have slightly lower energy than the others. The differences in energy levels in general are typically small; so the energy transfer direction is not unidirectional and many jumps between antenna pigments could occur before it ends up in the reaction centers that have the lowest energy levels. Other light-harvesting systems are, however, organized

slightly differently. In phycobilisomes of cyanobacteria and red algae, peripheral pigments have considerably higher energy levels than those closer to the reaction center, so energy transfer there is unidirectional.

The Protein Components

The Lhca and Lhcb proteins

There are 10 major LHC proteins in angiosperms, whose genes are designated Lhca1–4 and Lhcb1–6. The Lhca genes code for LHC proteins associated with photosystem I, whereas the Lhcb3–6 proteins associate with PS II. Lhcb1 and Lhcb2 serve as antenna for both photosystems. Although all these proteins share a common secondary structure with three membrane-spanning regions, embedded in the thylakoid membrane of the chloroplasts, their tertiary structure differ. Lhcb1, Lhcb2 that typically are much more abundant than the others, form together with Lhcb3 trimeric complexes, the Lhcb4–6 (commonly named CP29, CP26, and CP24) proteins are monomeric, and the Lhca proteins seem to form dimers. This organization is not static, for example, Lhcb1 and Lhcb2 can monomerize and Lhcb5 can form trimers. The true molecular weight of each protein varies only slightly between different plants, although the apparent mobilities change considerably with both plant species and gel systems used, but they all fall within the range of 20–30 kDa. Since several of the proteins typically comigrate, identification solely based on molecular weight is often not possible.

Structure of the LHCs

In the monomeric structure, two homologous membrane-spanning regions form the core of the complex. Closely associated with these are two carotenoid molecules that in the case of LHC II are lutein. A third membrane-spanning region is located more peripheral in the complex, and a short C-terminal helix, not spanning the membrane, is located on the luminal side of the complex. Fourteen chlorophyll molecules (eight chl *a* and six chl *b*) are bound to each monomer, with the head groups in the interior of the complex and the phytol tails protruding toward the surrounding membrane.

Organization of LHC II

The organization of the LHC proteins around PS II in the so-called 'PS II supercomplex' is shown in Figure 1. The monomeric CP29 and CP26 proteins associate most closely with the

Figure 1 Schematic representation of the photosystem II dimer including the peripheral antenna. D1 and D2 are reaction center polypeptides, CP43 and CP47 core antenna proteins, CP24, CP26, and CP29 are monomeric LHC proteins, and 1, 2, and 3 denote tentative positions of Lhcb1, Lhcb2, and Lhcb3 proteins, respectively, in the peripheral LHC II trimers.

core complex, and CP24 sits next to CP29. LHC II trimers (consisting of trimers of Lhcb1, Lhcb2, and Lhcb3 in different combinations) attach to the monomeric proteins, which thus form a bridge between the trimeric proteins and the core. In the supercomplex, only three trimers could attach to each PS II center. In low light conditions, there are more trimers functionally attached to each PS II, although they appear not to be so tightly bound to the supercomplex. Larger complex of trimers has been observed, but it is not known how abundant they are *in vivo* and to what they are associated.

Organization of LHC I

The subunit LHC proteins seem to bind to only one side of the PS I complex. Lhca1 and Lhca4 form a heterodimer, named LHCI-730 after its characteristic low-temperature fluorescence emission peak, and Lhca2 and Lhca3 may perhaps also form heterodimers. The latter two proteins have also, based on the fluorescence emission of isolated complexes, been named LHCI-680, although it is likely that they, in the purified forms, have lost chlorophylls emitting at long wavelengths that *in vivo* associate with the complexes, so this name is misleading. The long-wavelength-emitting chlorophylls make up a small portion of the total pool of LHC I pigments. These are kept in a chemical environment that results in an absorption shifted to longer (red) wavelengths and their role seems to be to allow use of wavelengths just outside of the visible spectrum to excite PS I, despite the fact that they have lower energy than that of the PS I reaction center. In addition to the LHC I subunits, a fraction of the LHC II trimers associates with PS I. The attachment site for these seems to be opposite to that of

LHC I; so excitation energy presumably transfers directly from the trimers to the PS I core, not via LHC I.

The Pigment Components

The pigment/protein stoichiometry of the LHC proteins has been surprisingly hard to determine. The LHC II trimer is a pigment-dense complex and may bind in total 24 chl *a*, 18 chl *b*, 6 lutein, 3 neoxanthin, and 3 violaxanthin molecule. CP29 may bind 7 chl *a*, 2 chl *b*, and one each of the three carotenoids, and CP26 one additional chl *b*. The individual Lhca proteins, on the other hand, may also associate with about 14 chlorophylls, one or two luteins, a small amount of violaxanthin and perhaps also trace amounts of β -carotene, a nonxanthophyll carotenoid. The functions of the carotenoids are more complex than those of the chlorophylls. Carotenoids are indeed antenna pigments, also harvesting lights at wavelengths (~ 500 nm) where the chlorophylls have a low absorptivity, enabling plants to efficiently utilize daylight, although the chlorophylls mainly absorb in the red and blue regions of the spectrum. In addition, they have an equally important function in photoprotection against excess light. Photoprotective processes are necessary in the antenna systems if the excitation energy is not able to quickly enter into the reaction centers but stays in the antenna system for prolonged times. This could, for example, happen if the energy-consuming reactions downstream of the photosynthetic light reaction are not able to utilize the energy in the same speed as it is generated, for example, if the system is at low temperature when enzymatic reactions are slow. This creates a block in electron flow away from the reaction centers that will not be able to accept another energy package from the antenna. Excited chlorophyll molecules can, via a triplet state, under such circumstances, produce singlet oxygen molecules that are highly reactive and thus dangerous for the system.

Mechanisms of Photoprotection

The molecular details behind the roles of carotenoids in photoprotection are not fully understood, but it involves both direct effects (quenching of reactive oxygen species) and an indirect effect, namely, an increase in energy dissipation in the antenna resulting in loss of excitation energy. This process, named 'feedback de-excitation' or 'qE type of nonphotochemical quenching', is mediated by PsbS, a protein related to the LHC proteins. Feedback de-excitation is triggered (within seconds) when the luminal pH drops below a certain point, as a result of photosynthetic proton pumping over the thylakoid exceeding the backflow through the ATP synthase complex. The PsbS protein is then protonated but the low pH does also bring about a change in the photosynthetic xanthophylls (the xanthophyll cycle), violaxanthin is converted to zeaxanthin via antheraxanthin by the enzyme violaxanthin de-epoxidase, activated by the low luminal pH. Zeaxanthin accumulates in the antenna and is also found free in the thylakoid membrane. Zeaxanthin could protect directly against oxygen radicals, but when zeaxanthin is bound to protonated PsbS, a conformational change takes place in the antenna, resulting in the creation of a highly quenching species that relieves the excitation

pressure from the system into heat, and thus contributes to photoprotection. Only a small fraction of the zeaxanthin formed is, however, associated with PsbS; most of the other LHC proteins can also have zeaxanthin bound to them, but whether this also contributes to photoprotection is not clear. Zeaxanthin is backconverted to violaxanthin when the light level drops. It appears also as if a role of this type of quenching is not restricted to zeaxanthin, although it is likely that under *in vivo* conditions, zeaxanthin is a major regulator of quenching.

Other Regulatory Roles

LHC II is also involved in another regulatory process, referred to as 'state transitions', based upon the different states of chl fluorescence that can be obtained by treating the plant with light of different quality. If the plant is exposed to light preferentially absorbed by PS I (wavelengths >680 nm) or normal light, the fraction of LHC II trimers functionally associated with the photosystems can change in order to create an even excitation pressure of the photosystems. Overcapacity of PS II leads to over-reduction of the interphotosystem electron carriers that, subsequently, leads to the induction of an LHC II kinase. Phosphorylation of LHC II results in a reduction of the PS II antenna size, releasing the system from the imbalance. There is a connection between light quality and quantity, LHC II phosphorylation, LHC II migration between the different thylakoid regions and the amount of *grana* stacking, but the details are not yet fully understood. In any case, the reversible phosphorylation takes place on a Thr or Ser residue close to the N terminus of the protein, which protrudes into the stroma. The phosphorylation leads presumably to a conformational change that, in turn, changes the properties of the complex.

The amount of LHC proteins varies considerably in different light regimes. Higher light results in decreased amounts of

LHC and, as a consequence, since chl *b* is confined to the LHC proteins, an increased chl *a/b* ratio of the plant. Hence, this ratio is an indicator of the amount of antenna protein and, thus, antenna size of the plant. This is an acclimation to the conditions when light harvesting is not limiting for photosynthesis. However, the different LHC proteins do not decrease simultaneously: the quantity of Lhcb1 and Lhcb2 (making up the bulk of the trimers) is most variable; but at full sunlight, Lhcb1 and Lhcb2 quantities are low, and the other LHC proteins also decrease in abundance.

Glossary

Amphipath A molecule that contains both polar, hydrophilic (water-loving) and apolar, hydrophobic (water-avoiding) groups that are spatially distinct, conferring a tendency to localize at and stabilize interfaces between water and oil phases.

Designer fat Dietary fats or fat substitutes that have been *de novo* synthesized or modified, either chemically or enzymatically, to achieve desired intestinal absorption ability, taste, and thermal or rheological properties.

Interface A quasi-two-dimensional phase between two bulk phases in which the physical environment of the molecules that comprise the region is distinct from the bulk phases.

Interfacial activation The process by which an enzyme increases its activity in the presence of an interface. For lipases it results from the combination of enzyme and substrate being oriented and concentrated at interfaces as a consequence of their amphipathic nature (the substrate theory) and from the conformational transition of the lipase to an open conformation as it binds to the interface (the enzyme theory).

Lipases are water-soluble, ester hydrolases that are traditionally defined by their marked preference for apolar, water-insoluble ester substrates. This group of enzymes also includes species referred to as cholesterol esterases. Lipases and cholesterol esterases are distinguished from phospholipases that catalyze the hydrolysis of acyl ester bonds of highly amphipathic phospholipids having an *sn*-glycero-3-phospho-X moiety and from carboxylesterases that hydrolyze polar, water-soluble esters. These distinctions are relative, however, because some lipases exhibit activity toward phospholipids or soluble esters. Typical natural lipase substrates include, in order of amphipathicity, long aliphatic chain acyl esters of cholesterol (cholesteryl esters), triacyl esters of glycerol (triacylglycerols), acyl esters of long chain alcohols (wax esters), diacyl esters of glycerol (diacylglycerols), and monoacyl esters of glycerol. Because lipase substrates tend to be oily and only weakly amphipathic, they reside primarily in a bulk oil phase in preference to the aqueous phase or to the interface, that is, monomolecular surface phase that separates the bulk oil and aqueous phases. It follows, because lipases are water-soluble enzymes, that the site of lipolysis is the quasi-two-dimensional interface. The focus of basic research on lipases has been to understand how a reaction involving such a change in dimensionality can occur and how it is regulated. Medically, lipases are targets for therapeutic intervention in the treatment of obesity. The focus of applied research with lipases has been to exploit the unusual properties of lipolytic systems for the production of chiral pharmaceuticals, improved detergents, and designer fats.

Roles of Lipases

In times of abundant energy supply cells accumulate triacylglycerols or wax esters as energy-storage depots. This is exemplified by adipose tissue in animals and by the formation of seed oils in plants. Cholesteryl ester storage provides a potential reservoir of cholesterol for steroidogenic tissues. Triacylglycerol

and cholesteryl ester accumulation also provides a mechanism of cellular defense by ameliorating the toxic effects of excess fatty acids and cholesterol. Most notable in this regard is the accumulation of cholesteryl esters in the arterial endothelium during atherogenesis. The mobilization of these bulk lipid inclusions intra- and extracellularly is catalyzed by lipases and cholesterol esterases. Once the ester bond is split, the more amphipathic hydrolysis products can be used metabolically or mobilized, in higher organisms, for transport among tissues. Because of the requirement, for hydrolysis for transport, lipases are key enzymes in maintaining lipid homeostasis in multiorgan animals and plants. For example, in mammals there are secreted gastric and pancreatic lipases for digesting dietary lipids. From the resulting hydrolysis products, long-chain fatty acids, and monoacylglycerols, triacylglycerols are resynthesized in the intestinal wall. These circulate in the form of lipoproteins that are then subjected to hydrolysis by lipoprotein lipase for entry into peripheral tissues and by hepatic lipase for entry into the liver, respectively. Within peripheral tissues (e.g., adipose tissue), triacylglycerols are resynthesized and, when needed, are mobilized by hormone-sensitive lipase/cholesterol esterase. The resulting fatty acids either re-enter the circulation for transport back to the liver for re-esterification or to organs such as muscle and heart for energy generation.

Hydrolysis Mechanism and Specificity

The catalytic domain of lipases contains both lipid-binding determinants and the active site. The core structure of the catalytic domain is an α/β -hydrolase fold, a motif common to other classes of hydrolases, that consists of β -sheets connected by α -helices. This supports a Ser-His-Glu/Asp catalytic triad resembling that of serine proteases and other hydrolytic enzymes. The active site serine is contained in a consensus sequence of Gly-X-Ser-X-Gly that forms a tight turn exposing the serine hydroxyl group to the scissile ester bond of the

substrate. The general mechanism of the reaction catalyzed by lipases is shown in **Figure 1**.

Substrate specificity among various lipases is variable because of the long flexible hydrocarbon-like groups that must be accommodated by the active site. This is in contrast to carboxylesterases that act on more soluble substrates and tend to have much more restrictive sites to accommodate a particular substrate. Lipases (e.g., pancreatic triacylglycerol lipase) that have relatively restricted substrate access to the active site tend to be specific for esters of primary alcohols, whereas others (e.g., *Candida rugosa* lipase) readily catalyze hydrolysis of esters of secondary alcohols as well. These latter enzymes are also more likely to exhibit activity against phospholipids and other nonconventional substrates. The list of atypical substrates includes peptides, simple amides, Schiff bases, (lyso) phospholipids, percarboxylic acids, and polyesters.

In addition to differing specificities for acyl and alkyl size, some lipases (e.g., *Rhizomucor miehei* lipase) show pronounced stereospecificity, whereas others (e.g., porcine pancreatic triacylglycerol lipase) do not. Interestingly, stereospecificity extends to prochiral molecules (e.g., trioleoylglycerol), in which the lipid substrate is symmetrical but the product of the reaction following removal of an acyl group from position 1 or 3 is chiral. Overall, there is interplay among the various types of specificity in lipases so that generalizations are difficult and specificity must be determined on a substrate-by-substrate basis. Also, the presentation of the substrate to the lipase can affect measured specificity. For pharmaceutical and other fine chemical applications, there have been extensive efforts to engineer lipases to carry out particular reactions with high stereospecificity.

Although lipases are defined and function *in vivo* as hydrolytic enzymes, they are increasingly employed industrially for *de novo* ester synthesis and acyl exchange. Most globular proteins, including lipases, will irreversibly denature if confronted with an interface between an aqueous phase and a highly

apolar phase (e.g., hydrocarbon-like). However, if water is removed from the enzyme to the extent that its chemical activity is reduced to very low levels, for example, by freeze-drying, the enzymes are stable and potentially active in an apolar medium. While this is true of many enzymes, it is particularly advantageous with lipases. This is because water is a reactant in the system (**Figure 1**) and because the substrates are nonpolar. The absence of water shifts the equilibrium of the reaction from ester hydrolysis to ester synthesis and the reactants are compatible with or can even serve as their own apolar solvent. This enables the synthesis of esters in high yield or the exchange of one ester acyl group for another (**Figure 1**).

Lipolysis Regulation

Physiochemical Importance of Interfaces

Lipases are classically defined as enzymes, generally monomeric and water soluble, that catalyze the hydrolysis of ester substrates that are apolar and, therefore, generally water insoluble. Although this definition indicates what lipases do, it does not reveal how they do it. The key to understanding how lipases work is to appreciate the role of the interface between the oil and water phases as an enabler of catalysis. This is shown schematically in **Figure 2**. Having ester functional groups, lipase substrates are more polar than simple hydrocarbons and have some tendency to partition between the bulk oil phase and the interface. Likewise, lipases will also partition to an oil–water interface from the aqueous phase. The consequence of these partitioning reactions is to orient and concentrate the substrate and enzyme together in a quasi-two-dimensional phase. This phenomenon is known as the substrate theory of why lipases are more active on insoluble substrates than soluble ones. In this view of lipolysis, the interface assumes part of the role played by classical enzyme–substrate binding in solution, but in a nonspecific way.

Figure 1 Lipolysis mechanism. E–O–H represents the active site serine which forms the acyl-enzyme intermediate in catalysis. The interchangeability of H, R', and R'' shows that lipases readily catalyze ester synthesis, ester hydrolysis, and acyl exchange, depending on the activity of water in the system, and the circular bond in the lower right structures indicates that the carboxyl oxygen atoms become randomized during the catalytic cycle.

Figure 2 The interfacial nature of lipolysis. The substrate (S) is initially present in or as an oil droplet (shaded) whereas the lipase (E) is in the aqueous phase. Catalysis requires that both E and S partition to the interface. Partitioning of E involves a conformational change with the bound species noted as E*. Reaction products (P) will remain in the interface or partition to the oil phase, depending on their amphipathicity.

The most important consequence of enzyme and reactant partitioning is that the instantaneous rate of lipolysis depends on the two-dimensional concentrations of enzyme and reactants in the interface rather than their concentrations in either of the bulk phases.

This sequential scheme for lipolysis has other consequences as well. For a substrate, it means that its amphipathicity, together with its bulk concentration in the oil phase, will contribute to its two-dimensional concentration in the interface. Simplistically, if one had an equimolar mixture of glycerides in an oil phase, their interfacial concentrations would be in the relative order monoacylglycerols > diacylglycerol >> triacylglycerol. Measuring initial rates of hydrolysis for this mixture using a hypothetical lipase with no positional specificity, and normalizing for the number of ester bonds available would show this same apparent order leading, incorrectly, to the conclusion that the lipase is specific for monoacylglycerols. Another consequence of the interfacial nature of lipolysis is that the reaction products will accumulate in the interface, unless they are removed by partitioning into the oil phase or are solubilized in the aqueous phase. With respect to the latter, albumin or cyclodextrins are often used *in vitro* to trap fatty acids and monoacylglycerols in the aqueous phase during the hydrolysis of tri- or diacylglycerols. When it occurs, the accumulation of reaction products in the interface enriches the interface in more amphipathic molecules, greatly complicating the measurement of specificity and interpretation of kinetic data. Product accumulation can also have the effect of slowing the reaction due to fatty acid accumulation while at the same time causing the area of the interface to expand. Area expansion will have the opposite effect by favoring the partitioning of more lipase to the interface. Thus, once lipolysis is initiated in a system having a bulk oil phase as well as an aqueous phase, the regulation of lipolysis rate and extent becomes extremely complex. It is for this reason that researchers have utilized simpler systems, like mono-molecular lipid films, in efforts to understand lipase regulation.

That lipolysis is heterogeneous, unequivocally demonstrated by the P. Desnuelle group in 1965. They showed that if the same insoluble substrate was presented to a lipase as coarse and fine dispersions in buffer, the apparent Michaelis constant for the reaction (i.e., the three-dimensional concentration of substrate at which the hydrolysis rate was half maximal) was lower for the fine dispersion. However, if the rate data were analyzed as a function of total substrate particle surface area rather than bulk substrate concentration, the constant was the same for both dispersions. This occurred because the two-dimensional concentration of substrate at the particle interface was actually the same for the coarse and fine dispersions and the observed saturation of reaction rate with increasing substrate dispersion reflected saturation of lipase partitioning to that surface with increasing interfacial area. Despite the complexity of lipolysis kinetics arising from the interfacial nature of the process, it has been possible to develop kinetic schemes for analyzing lipase kinetics, at least for simple experimental systems, for example, where reaction products are removed from the interface when formed. These are valuable for screening potential lipase inhibitors to determine the efficiency at which each step of the reaction (i.e., partitioning or interfacial catalysis) contributes to the observed inhibition.

Structural Adaptation of Lipases at Interfaces

It might be presumed that lipases would possess a high affinity for lipid–water interfaces, that is, that they would be highly amphipathic. However, their affinities toward interfaces dominated by amphipathic lipids, such as phospholipids, is often no higher than that of other water-soluble globular proteins. Indeed, many lipases can be isolated as soluble monomeric proteins that do not show a propensity to aggregate. However, if exposed to a surface of a pure substrate, such as triacylglycerol, lipases bind with high affinity. Related to this observation is their ability to efficiently catalyze the hydrolysis of insoluble substrates, but not soluble ones. To explain this observation, it was proposed early on that lipases somehow became activated at interfaces. In the 1990s, the determination of lipase structures under varying conditions revealed the physical basis of this phenomenon (Figure 3). In aqueous solution the active site of most lipases is not exposed to the medium but lies in the interior of the protein under a lid or flap structure. This keeps soluble ester substrates away from the catalytic triad. As implied by its name, the lid can open to reveal the active site and, simultaneously, to create and expose a large area comprised of hydrophobic amino acids. Whereas this open conformation is energetically unfavorable in the aqueous phase, it may be induced or trapped by the presence of an apolar surface. The lipase then binds with high affinity to the interface; the active site is accessible for diffusion of substrate molecules into it and catalysis can proceed. It is the conformation of this open form of the enzyme that determines specificity for

Figure 3 Closed and open conformations of pancreatic triacylglycerol lipase. The backbone structure of the lipase is shown in light blue-green with the C2 regulatory domain on the left and the catalytic domain on the right. Nonpolar (green) and polar/charged (red) residues in the vicinity of the catalytic triad (yellow) are shown space filled. Note that in the closed conformation, presumed to exist in solution (left) and designated E in Figure 2, mostly polar/charged residues are exposed to water and the catalytic triad is shielded from water. In the closed conformation, presumed to exist at the interface and designated E' in Figure 2, a large, apolar surface is exposed on the top of the molecule as shown and the catalytic triad becomes accessible from the top. This surface presumably interacts with the substrate-containing oil droplet. The closed structures were drawn from coordinates kindly provided by Dr. C. Cambillau and the open structure from the Protein Data Base, file 1LPA.pdb.

particular substrates. The changing of conformation by lipases in the vicinity of an interface is known as the enzyme theory of why lipases are more active on insoluble substrates than on soluble ones. It should be noted that the enzyme theory of lipolysis and the substrate theory of lipolysis described above are not mutually exclusive.

A still unresolved question is what kind of a surface a lipase needs for surface binding in the open conformation. Natural interfaces tend to be dominated by phospholipids and proteins. These are necessary to emulsify the apolar lipid substrate, that is, to stabilize it in a dispersed state with high surface area, but tend to inhibit lipase binding to the interface. Research suggests that lipases need a defect- or a patch-free binding inhibitor in the interface to initiate lipolysis. Once bound, the generation of lipolysis proceeds and its reaction products increase the number of binding sites and more lipase molecules can bind. Thus, lipolysis often appears to be autocatalytic in the presence of inhibitory phospholipids or proteins, that is, there is an initial lag in lipolysis followed by a burst. Overcoming the inhibition of lipases by amphipathic lipids and proteins is important to understand not only their roles and regulation *in vivo*, but also their applications, for example, improve the efficiency of detergents.

Lipase Regulatory Domains

Many lipases, such as gastric lipase, consist of a single protein domain but others have a second domain connected to the catalytic domain by a flexible linker. The most studied of these are members of the lipase gene family, exemplified by pancreatic triacylglycerol lipase (Figure 3), lipoprotein lipase, and hepatic lipase. These have a C2 domain, a motif common to other peripheral (also called amphitrophic) proteins, that is, proteins that reside in solution but translocate to and function at a lipid–water interface in response to a signal. The C2 domain framework is an eight-stranded, antiparallel β -sandwich with connecting loops. In lipases having C2 domains one of these loops exposes hydrophobic amino acid side chains, such as leucine, tyrosine, and tryptophan. These confer an amphipathic character to the domain and, depending on assay conditions, can be essential for lipase activity to be expressed. Given the large hydrophobic surface created near the active site of the catalytic domain by the opening of the lid, such dependence on a C2 domain for initiating lipolysis suggests that it is needed to associate the enzyme with a substrate-containing interface long enough for catalytic domain to open and lock the enzyme on the interface.

Lipase Cofactors

Two members of the lipase gene family, pancreatic triacylglycerol lipase and lipoprotein lipase, utilize cofactor proteins for

carrying out efficient lipolysis. As noted above, lipase interface binding tends to be inhibited by those molecules that help create and stabilize interfaces, such as phospholipids. Cofactor proteins facilitate the initiation of lipolysis at such interfaces. The traditional view of cofactors has been that they are amphipathic proteins that simply bind both the interface and the lipase and thereby anchor the lipase to the interface. However, the comparable affinities of lipases and their cofactors for protected interfaces suggest that they do more. Structural studies of the complex between pancreatic lipase and its protein cofactor, colipase, show that the cofactor may facilitate the opening of the lid through protein–protein interactions with the open conformation of the catalytic domain of the enzyme. Another role has been suggested by comparison of the ability of the cofactor to bind to interfaces with different compositions. Specifically, if a phospholipid-rich interface also contains the substrates and products of lipolysis, colipase binding is strengthened. This occurs because the colipase molecules tend to laterally concentrate the nonphospholipid molecules in their vicinity. In this manner, they help to create a nanometer-sized region from which phospholipid tends to be excluded. This facilitates lipase binding by a combination of lipid–protein and protein–protein interactions and thereby helps initiate lipolysis. Another speculative role for lipase cofactors is that their preference for binding to substrate-containing surfaces acts to target lipase to those surfaces in preference to interfaces that do not contain substrate.

Glossary

Biological membranes A thin shell surrounding either internal compartments in cells or the entire cell. Composed of special proteins and lipids.

Lipids Small biomolecules with hydrophobic characteristics.

Polar headgroup The portion of a lipid molecule that interacts with aqueous solution; it usually contains several chemical groupings that can hydrogen-bond with water.

Chemical Structure of Bilayer-Forming Lipids

Lipid bilayers are composed primarily of polar lipids. Glycerophospholipids and sphingolipids are usually the predominant polar lipids in natural membranes. Unlike dietary lipids (fats), these molecules possess a highly polar headgroup in addition to (two) nonpolar (i.e., hydrophobic) tails ([Figure 1](#)).

The hydrophobic tails consist of the hydrocarbon chain portions of fatty acids and/or the base sphingosine. Hydrocarbon chains are linear in eukaryotic organisms, but sometimes have branching methyl groups in bacteria.

The polar headgroups of the lipids can have various chemical structures. Often they contain phosphate to which a polar or charged alcohol derivative is attached. In other cases they contain carbohydrates. The polar headgroup can be electrically neutral, zwitterionic, or negatively charged.

In eukaryotes, sterols such as cholesterol are also major components of the bilayer. Sterols differ from other polar lipids in having a simple, small hydroxyl group as their polar portion. This hydroxyl group is attached to four fused aliphatic hydrocarbon rings. In addition, they contain a branched hydrocarbon chain that is attached to the end of the rings opposite the hydroxyl.

Organization of Lipids in Bilayers

In bilayers lipids orient such that their polar groups are in contact with the aqueous environment and their hydrocarbon segments face each other ([Figure 1](#)). As a result, the polar groups in each half of the bilayer (called a monolayer or leaflet) face away from one another. As one moves from the aqueous solution to the bilayer center, a somewhat ill-defined gradient of decreasing polarity is encountered.

The formation of the bilayer is driven by the hydrophobic effect, which is conventionally thought of as primarily a decrease in water-free energy that occurs when the clustering of hydrophobic groups allows them to avoid contact with water molecules. Because of the shape of polar lipids, they usually form topologically closed bilayers, for example, a spherical or elliptical shell. Such closed structures eliminate direct contact between lipid hydrocarbon and water. They contain an internal aqueous lumen separated from the external aqueous solution by the bilayer. Artificially formed bilayers of this type are called liposomes. The bilayer plus the internally trapped aqueous solution

is known as a vesicle ([Figure 2](#)). Vesicles can contain one lipid bilayer, in which case they are said to be unilamellar vesicles, or multiple bilayers each separated by thin layers of aqueous solution, in which case they are called multilamellar vesicles. Flattened stacks of bilayers with the internal aqueous solution largely squeezed out can also be prepared.

Membrane Proteins and Bilayers

Natural membranes are associated with numerous proteins. These proteins that span the lipid bilayer are said to be transmembraneous ([Figure 2](#)). Non-transmembraneous proteins associated with the polar surface of the bilayer are also present ([Figure 2](#)). Proteins can have a significant influence on membrane structure. For example, they are likely to be responsible for the distortion of natural membranes into more complex shapes than those observed for pure lipid bilayers. Familiar examples are the membranes of red blood cells and the variable-shape membranes surrounding amoeba. On the other hand, it is clear that natural membranes contain bilayers that have physical properties similar to those of pure lipid bilayers. The fact that the lipid-facing amino acid residues of membrane proteins form hydrophobic surfaces that match lipid dimensions is no doubt an important factor explaining this behavior. Nevertheless, the physical properties of the hydrophobic segments of membrane proteins are very different than those of lipids and the consequences of these differences remain to be fully explored.

Bilayer Dimensions

Experiments on liposomes show that the diameter of spherical lipid bilayers can be any value upward from 250 Å. Bilayer width (thickness) is determined by the length of the nonpolar tails of the polar lipids and sterols. This usually ranges from 16 to 24 carbon atoms for the hydrocarbon chains of phospholipids and sphingolipids. Combined with the effects of lipid state and double bonds (see below), this results in a hydrocarbon core of the bilayer that is ~30 Å in width. Total width including the lipid headgroups is on the order of 45–50 Å, but the exact value depends on the structure of the lipid polar headgroups, which can be very large in some cases.

Figure 1 Schematic representation of cross section through a lipid bilayer composed of a single type of phospholipid or sphingolipid. Polar headgroups are illustrated as circles and hydrocarbon tails are shown as lines. Notice each lipid has one headgroup and two tails. A bilayer composed of both a disordered liquid domain (left) and an ordered gel domain (right) is illustrated.

Figure 2 A unilamellar lipid vesicle formed by a lipid bilayer and containing one transmembrane protein (striped) and one protein associated with the lipid polar headgroups (filled).

Relationship between Bilayer Form and Bilayer Function

The properties of bilayers are admirably suited to their biological function. The closed structure of the bilayer allows biological membranes to completely encase cellular contents (such as nucleic acids, proteins, sugars, and amino acids) in a hydrophobic barrier that prevents them from escaping into the surrounding solution.

The width of the bilayer is such that proteins of ordinary size are able to span the lipid bilayer. This allows membrane proteins to maintain contact with both the internal and external aqueous milieu. As a result, membrane proteins

can carry out functions such as the transport of molecules across bilayers. Such abilities are central to membrane function. A bilayer that was much wider than that formed by natural lipids (i.e., one formed by much longer fatty acid chains) would require the metabolically wasteful synthesis of extra-large transmembrane proteins as well as that of longer lipids. A bilayer that was significantly thinner than that formed by natural lipids would not be stable.

Physical State of Bilayer Lipids

Another important property of lipid bilayers is their ability to exist in different physical states (or phases). At low temperatures bilayers often exist in a relatively solid-like state called the gel or $L\beta$ state or phase. At higher temperatures gel-state bilayers undergo a melting transition and the gel state is replaced by a more disordered, liquid-like state, variously designated as the liquid-crystalline, liquid-disordered, or $L\alpha$ state. Melting temperatures (or if temperature is decreased, freezing temperatures) depend on the structure of both the hydrophobic tails and the polar headgroups of the individual lipid molecules. The melting temperature of lipids with linear saturated tails, which contain only single bonds connecting carbon atoms to each other, is much higher than that of lipids with unsaturated tails, which have *cis* double bonds, as well as single bonds. Because sphingolipids tend to contain hydrocarbon chains lacking *cis* double bonds, they tend to have much higher melting temperatures than glycerophospholipids, which tend to have more highly unsaturated hydrocarbon chains.

Bilayers containing sterols can exist in a third lipid state called the liquid ordered or L_o state. This state is observed most frequently in mixtures of sterols with relatively saturated chain polar lipids. The L_o state has properties that are intermediate between the disordered liquid and gel states.

Studies in synthetic lipid bilayers show that in a single bilayer, different regions (known as domains) can exist in different physical states (Figure 1). It is believed that the disordered liquid state is by far the most common state present in biological membranes. However, in eukaryotic cells it is now thought that ordered liquid-state domains can coexist with disordered liquid domains. L_o state domains in cell membrane, called lipid rafts, are rich not only in sphingolipids and sterols, but also in special subsets of membrane proteins. Rafts appear to have a specialized role in a number of important biological processes.

The Effect of Lipid State upon Lateral Organization of Lipid Molecules

Lipid bilayers in different physical states differ in a number of properties. One is the degree of lateral interaction between various bilayer lipids. In the disordered liquid-like state, bilayers are believed to exist as a more-or-less random mixture of various lipid species. In other words, there are few or no cases in which tight associations between two different lipid molecules occur. As special constraints tend to be much more restrictive in solids, a much higher degree of lateral organization is likely to exist in a gel-state bilayer containing a mixture

of different lipids. This is little studied except to the extent that it appears that separate gel-phase domains with different lipid compositions can coexist in a single bilayer. The nature of lateral interactions between different lipids in the liquid-ordered state is being actively studied, but remains unclear. There may be specific arrangements of sterol molecules relative to the other polar lipids present in the bilayer, and various liquid-ordered domains with different compositions may be able to coexist in a single bilayer.

Interactions between each of the monolayers within a single bilayer are also poorly understood in most cases. Under some conditions certain combinations of hydrocarbon chain lengths allow interdigitation of hydrocarbon chains from opposite monolayers.

Influence of Physical State on Lipid Conformation and Lateral Diffusion

The conformation of individual lipid molecules within a bilayer is also dependent upon lipid state. In all states, the hydrocarbon chains of the lipids tend to align parallel to one another and perpendicular to the surface. A high degree of parallel alignment characterized by the presence of tightly packed lipids occurs in the gel- and liquid-ordered states. In contrast, in the disordered liquid state, lipids are more loosely packed and the degree of alignment is reduced because carbon-carbon single bonds can twist a manner that results in bending of the hydrocarbon chains. This also results in the bilayer being thinner than in other states (Figure 1). The relatively random location of such bends within a hydrocarbon chain results in increased disorder as one moves from the bilayer surface toward the bilayer center. There is also a contribution to disorder from the presence of double bonds. These are usually in the form of *cis* double bonds, which form permanent bends in hydrocarbon chains. Headgroup conformation, and its dependence on lipid state, are more poorly characterized in most cases.

Another property of bilayers that depends on lipid state is lateral diffusion. This refers to random sliding motions of lipids within the plane perpendicular to the average direction of the hydrocarbon tails. Lateral motions are rapid in both the liquid-disordered and liquid-ordered state, but much reduced in the gel state. It should be emphasized that the ability to undergo relatively rapid lateral motions is an important feature of biological membranes. It allows membrane components to rearrange within the lipid bilayer such that they can form and break functionally important complexes.

Transverse Lipid Movements

Lipids can also undergo transverse movement, in which they move (or flip) from one monolayer of the bilayer to the opposite one. For good reason this motion is many orders of magnitude slower than lateral diffusion. Transverse flipping requires that the polar/charged portions of lipids transiently dissolve within the hydrophobic core of the bilayer. This is very unfavorable energetically. However, it should be noted that in natural membranes specific flippase proteins are believed to catalyze rapid flipping events in some cases. Furthermore, it appears that spontaneous flipping is more rapid for sterol molecules, which have a headgroup that is very small and not excessively polar, than it is for most phospholipids and sphingolipids, although this remains an area of some controversy.

Effect of Lipid Bilayers on Local Aqueous Environment

Finally, it is important to remember that lipid bilayers can also affect the structure of their immediate aqueous environment. When a significant fraction of lipids in a bilayer is anionic, they tend to attract significant numbers of cations while repelling anions. As a result a special double layer of solution depleted in anions and enriched in cations surrounds the bilayer. This layer can alter the structure and function of membrane proteins.

Glossary

Farnesyl A 15-carbon isoprenoid unit attached via thioether linkage to proteins.

Fatty acylation The process whereby fatty acids are covalently attached to proteins.

Geranylgeranyl A 20-carbon isoprenoid unit attached via thioether linkage to proteins.

GPI anchor A complex structure consisting of ethanolamine phosphate, 3 mannoses, *N*-acetylglucosamine, and phosphatidylinositol.

Myristoylation The process whereby myristate, a 14-carbon fatty acid, is covalently attached to the N-terminal glycine of a protein.

Palmitoyl acyltransferase (PAT) An enzyme that catalyzes attachment of palmitate to proteins.

Palmitoylation The process whereby palmitate, a 16-carbon fatty acid, is covalently attached to a residue (usually cysteine) within a protein.

Prenylation The process whereby isoprenoid groups are covalently attached to a cysteine residue in a protein.

Rafts Membrane regions that are enriched in cholesterol and sphingolipids.

S-acylation Attachment of a fatty acid, typically palmitate, via thioester linkage to a cysteine residue within a protein.

Lipid Modification of Proteins

Three different types of lipid moieties are typically found attached to proteins: fatty acids, isoprenoids, and glycosylphosphatidyl inositol (GPI) anchors (Figure 1 and Table 1). Linkage of each of these groups occurs within different protein sequences and is catalyzed by different enzymes.

Fatty Acylation

The two major types of fatty acids that are attached to fatty acylated proteins are myristate and palmitate. Myristoylation occurs exclusively at the N-terminus, so only one myristate can be attached to a given protein. Palmitate is usually attached to proteins at internal cysteine residues. Proteins can be fatty acylated with one or several palmitates or with both myristate and palmitate.

Myristoylation

Myristate is a 14-carbon saturated fatty acid that is directly linked to the N-terminus of select proteins in a process known as N-myristoylation. Approximately 0.5% of all proteins in eukaryotes are modified in this manner; in humans, this corresponds to about 150 proteins. Nearly all N-myristoylated proteins begin with the sequence Met-Gly. During protein translation, the initiating methionine is removed by methionine aminopeptidase, exposing glycine at the N-terminus. The fatty acid is then linked to the protein via an amide bond between myristate and the N-terminal glycine residue. Additional amino acids near the N-terminus are important for determining whether a protein becomes N-myristoylated. Algorithms that predict with high accuracy whether a particular protein sequence is N-myristoylated are available on the Internet. The high stability of the amide linkage makes N-myristoylation an essentially irreversible protein modification.

N-myristoylation is catalyzed by the enzyme N-myristoyl transferase (NMT). Most organisms have one or two NMT genes, and NMT has been shown to be an essential gene product that is required for the growth of fungi, flies, and plants. The N-myristoylation reaction occurs in a cotranslational manner, that is, while the newly translated polypeptide is still attached to the ribosome. The preferred fatty acid substrate for NMT is myristoyl-CoA, an activated form of myristate. Fatty acids that are shorter or longer than myristate are generally not transferred from their respective fatty acyl-CoAs to proteins. However, NMT will transfer unsaturated 14 carbon fatty acids to proteins, a process that occurs primarily in the retina.

The requirement for a free N-terminal glycine prevents N-myristoylation from occurring on internal glycines within the polypeptide chain. However, during apoptosis, caspase-mediated protein cleavage generates newly exposed N-termini which, if they contain Gly within a consensus sequence, can serve as posttranslational targets for N-myristoylation. Proteins modified in this manner, termed 'morbid myristoylation' include BID, actin, and gelsolin.

Palmitoylation

Several hundred eukaryotic proteins are posttranslationally modified by covalent attachment of the 16-carbon fatty acid palmitate. The fatty acid is generally attached to one or more cysteine residues within the protein through a thioester linkage, and this process is referred to as S-palmitoylation. Palmitoylation can occur within a variety of types of protein sequences: (1) at or near the transmembrane domain of a membrane protein; (2) near a C-terminal prenylated cysteine (see later); (3) near the N- or C-terminus; (4) adjacent to or near an N-terminal myristoylated glycine; or (5) at an N-terminal cysteine via an amide bond. To date, there is no definitive consensus sequence for protein palmitoylation, but Web-based algorithms can be used to make predictions of potential palmitoylation sites.

Figure 1 Structures of lipid-modifying groups on proteins. Structures of the different lipid modifying groups and their linkages to proteins are depicted. For the GPI anchor, Inos = inositol, GN = *N*-acetylglucosamine, and M3 = 3 mannoses.

Table 1 Examples of lipid-modified proteins

Fatty acylated

Myristate

Src family kinases, G α subunits, Arf, Recoverin, MARCKS, mammalian retroviral Gag proteins, calcineurin B, eNOS, cytochrome b5 reductase, AKAP

Palmitate

Transferrin receptor, CD4, caveolin-1, G-protein-coupled receptors (GPCRs), H-Ras, N-Ras, G α subunits, GAP43, PSD-95, Src family kinases, Huntingtin, eNOS, SNARE proteins

Prenylated

Farnesyl

H-Ras, K-Ras, N-Ras, prelamin A, Rheb, CENP-E, CENP-F

GeranylGeranyl

G γ subunits, Rho family proteins, Rab proteins, RalA, RalB

GPI-anchored

Alkaline phosphatase, acetylcholinesterase, CD55 (DAF), CD59, 5'-nucleotidase, Thy-1, PrP^C prion protein, trypanosomal VSG, NCAM

The fatty acid donor for protein palmitoylation is palmitoyl-CoA. In eukaryotic cells, two main families of palmitoyl acyl transferases (PATs) catalyze attachment of palmitate to proteins: DHHC PATs and MBOAT PATs. DHHC PATs are multipass membrane proteins with a cysteine-rich domain that contains a conserved sequence, Asp-His-His-Cys. Seven DHHC PATs are expressed in *S. cerevisiae* and these are responsible for nearly all the protein palmitoylation in the yeast cell. At least 23 DHHC enzymes are present in the human genome, many of which have recently shown to exhibit distinct substrate specificity. The MBOAT (membrane-bound O-acyl transferase) family contains two members, Hhat and Porc, which mediate palmitoylation of secreted proteins. Both Hhat and Porc are transmembrane proteins that are predicted to traverse the bilayer 8–12 times. Hhat palmitoylates the hedgehog family of proteins on an N-terminal cysteine that is exposed after signal-sequence cleavage. Hedgehog protein modification is unusual in two respects. First, unlike nearly all other palmitoylated proteins, the link between palmitate and hedgehog

is an amide bond. Second, hedgehog proteins undergo an additional lipid modification, covalent attachment of cholesterol to the C-terminus of the mature, processed protein product. Both of these modifications are required for hedgehog signaling function. A different MBOAT PAT, Porcupine (Porc) has been implicated in mediating palmitoylation of Wnt and Wingless proteins. At least two fatty acylation reactions have been ascribed to Porc: attachment of palmitate to a cysteine residue (Cys77 in Wnt3a) via thioester linkage, and attachment of palmitoleic acid (16:1) to a downstream serine residue (Ser209 in Wnt3a). Palmitoylation at both sites regulates Wnt secretion and signaling.

Acylation with other fatty acids

In addition to palmitate, lipidated proteins can contain other longer- or shorter-chain fatty acids. These include saturated (stearate), and unsaturated (arachidonate and palmitoleic acid) fatty acids. The alternative fatty acids may be attached at the same position as the palmitoylation site or at a different site. At least one protein, the appetite-stimulating hormone ghrelin, has been reported to be modified by attachment of the 8-carbon fatty acid oleate to a serine residue at position 3. Acylation of ghrelin is catalyzed by GOAT (Ghrelin O-acyltransferase), an MBOAT family member that shares homology with Hhat and Porc.

Prenylation

Protein prenylation is a posttranslational modification that occurs in the cytosol. In the human genome, over 200 proteins are predicted to be modified by prenylation. Prenyl groups are built from 5-carbon building blocks known as isoprene. Prenylation involves the attachment of two types of isoprenoid groups, 15-carbon farnesyl or 20-carbon geranylgeranyl, via thioether linkage to a cysteine residue at or near the C-terminus. The prenyl group donors for these reactions are farnesyl diphosphate and geranylgeranyl diphosphate, respectively. Most prenylated proteins contain a CAAX box sequence at their C-terminus (C = Cys, A = aliphatic amino acid, X = any amino acid). The identity of the C-terminal amino acid

determines whether the protein is recognized by farnesyl transferase (FTase) (X = Met, Ser, Ala, or Gln) or geranylgeranyl transferase I (GGTase I) (X = Leu or Phe). PrePS is a Web-based algorithm that can be used to predict whether a protein will be farnesylated or geranylgeranylated. FTase and GGTase I are heterodimers consisting of a common α subunit and a distinct β subunit. Following prenylation of the CAAX box, two additional modifications occur in the ER. The three C-terminal amino acids are cleaved by the endoprotease Rce1, and the prenylated C-terminal cysteine is carboxymethylated by the carboxymethyltransferase pcCMT/Icmt. A third prenyl transferase, Rab GGTase or GGTase II, attaches geranylgeranyl to Rab proteins that terminate with -CC, CXC, CCX, or CCXX sequences. Rab proteins must be bound to Rab Escort Protein (REP) in order to be prenylated by GGTase. Genetic mutations in REP cause choroideremia, a disease characterized in humans by retinal degeneration and blindness.

GPI Anchors

GPI anchors are attached to the C-termini of approximately 1% of all eukaryotic proteins. These complex structures consist, in general, of ethanolamine phosphate, three mannoses, *N*-acetylglucosamine, and phosphatidylinositol (PI). At least 20 enzymes are involved in the synthesis and attachment of GPI anchors, a process that occurs in the endoplasmic reticulum (ER) membrane. A C-terminal hydrophobic region in the target protein serves as a signal for GPI anchor attachment. This sequence is cleaved and replaced with the GPI anchor at the C-terminus in a reaction catalyzed by GPI transamidase, a complex consisting of five membrane-bound proteins. The modified protein is transported through the Golgi apparatus and ultimately to the extracellular leaflet of the plasma membrane. Putative GPI-modified proteins can be predicted using the algorithm mentioned in the 'Relevant Websites' section.

GPI anchors can undergo remodeling reactions that change the structure of the anchor. An acyl chain attached to the diacylglycerol moiety of inositol is removed and replaced with a longer-chain fatty acid. This lipid remodeling event promotes transport of the GPI-modified protein from the ER to the Golgi and is required for interaction of the protein with lipid rafts. Many GPI-anchored proteins of fungi undergo an additional processing event after delivery to the outer leaflet of the plasma membrane. The GPI anchor is cleaved between a mannose and the *N*-acetylglucosamine moiety, removing the inositol lipid portion. The remainder of the modified protein is then cross-linked to sugar residues in the cell wall.

Detection of Lipid-Modified Proteins

Mass spectroscopy analysis provides definitive identification of the modifying group on proteins. Fatty acylated and prenylated proteins can be detected by radiolabeling cells with ^3H - or ^{125}I -labeled fatty acids or isoprenoid precursors, followed by isolation of the protein with a specific antibody and autoradiographic analysis. Alternatively, chemical labeling using acyl-biotinyl exchange, azido-fatty acids, or click chemistry has recently been developed. A hallmark of many GPI-anchored proteins is that they can be released from the cell surface by *in vitro* cleavage with PI-specific phospholipase

C (PI-PLC); this process occurs *in vivo* for certain GPI-anchored proteins (e.g., alkaline phosphatase). However, other GPI-anchored proteins have palmitate attached to the inositol ring, making them resistant to PI-PLC cleavage.

Membrane Targeting of Lipid-Modified Proteins

Lipid modifications play important roles in promoting interaction of proteins with membranes. The nature of the lipid group determines how the modified protein will traffic through the cell, how tightly the protein will bind to a membrane, and which membrane it will bind to. Membrane targeting is essential for the function of many types of lipid-modified proteins. Localization of proteins to a membrane increases their local concentration and amplifies the efficiency of interaction with other membrane-bound substrates and targets. When lipid modification is inhibited, the affected proteins are mislocalized within the cell and no longer function effectively.

Membrane Binding

The presence of a molecule of palmitate, geranylgeranyl, or a GPI-anchor is sufficient for membrane binding of the modified protein. By contrast, the hydrophobicity of myristate or farnesyl is not sufficient to stably anchor a protein to the membrane. *N*-myristoylated and farnesylated proteins that do not contain a transmembrane domain need to use a second signal to promote membrane binding. The second signal is either a cluster of basic amino acids (lysine or arginine) or covalently bound palmitate contained within the protein. The positively charged basic cluster provides electrostatic interaction with negatively charged lipids, such as phosphatidylserine and phosphatidylinositols, which are enriched on the cytoplasmic surface of the plasma membrane. Synergy is achieved by combining the two forces, hydrophobic and electrostatic, resulting in enhancement of membrane binding by several orders of magnitude. Myristoylated proteins that utilize a myristate + basic motif for membrane binding include Src, MARCKS, and HIV-1 Gag, whereas K-Ras4B is the prototype for proteins with a farnesyl + basic membrane-binding mechanism.

Attachment of palmitate to a myristoylated or prenylated protein can also be used as a second signal to enhance hydrophobic interactions with the phospholipid bilayer. Examples include members of the Src family of tyrosine protein kinases, which are dually fatty acylated with myristate and palmitate, and H-Ras and N-Ras, farnesylated proteins that contain one (N-Ras) or two (H-Ras) additional palmitate moieties attached to cysteine residues just upstream from the prenylated C-terminus. Palmitoylation of these proteins is typically dependent on prior lipid modification, most likely because myristoylation or farnesylation enhances the ability of the protein to interact with a membrane-bound PAT. The combination of two lipid groups provides sufficient binding energy to promote binding of the modified protein to a membrane.

Reversible Membrane Binding and Switch Mechanisms

Several mechanisms exist *in vivo* to regulate membrane binding of lipid-modified proteins. The first is removal of the

modifying group. As indicated above, some GPI-anchored proteins can be released from the membrane after cleavage of the GPI-anchor by PI-phospholipase. S-Palmitoylation is a reversible reaction; palmitate is removed from proteins by palmitoyl protein thioesterases. The reciprocal action of PATs and thioesterases sets up a dynamic balance of palmitoylation/depalmitoylation reactions in the cell. As a consequence, proteins that are S-palmitoylated undergo reversible cycles of membrane association and dissociation.

Myristoylated and prenylated proteins contain stable lipid-protein linkages and are thus not subject to this mode of regulation. Instead, exposure of the modifying group can be regulated by a switch mechanism. For example, recoverin and Arf are N-myristoylated proteins whose membrane binding is regulated by an intramolecular myristoyl switch. These proteins exist in two conformations. In one conformation, myristate is hidden within a hydrophobic pocket inside the protein, and the protein is cytosolic. Binding of ligand triggers the myristoyl switch: a conformational change results in exposure of myristate and promotion of membrane binding. An electrostatic switch is another mechanism to regulate membrane-binding activity of either myristoylated or farnesylated proteins that contain a polybasic cluster. Phosphorylation of serine or threonine residues within the polybasic motif introduces negative charge. As a result, the electrostatic forces that were contributing to membrane binding are diminished, and the phosphorylated protein is released from the membrane. MARCKS and K-Ras4B are examples of myristoylated and farnesylated proteins, respectively, that undergo electrostatic switch-dependent release from the membrane upon phosphorylation by protein kinase C.

Switches that regulate the exposure of prenyl groups have been described, but these mechanisms involve intermolecular interactions. Rho and Rab are membrane-bound proteins that are geranylgeranylated at their C-termini. Upon interaction with specific guanine nucleotide dissociation inhibitor (GDI) proteins, the isoprene units become sequestered within a hydrophobic cleft of the GDI, inducing extraction of the Rho:GDI or Rab:GDI complex from the membrane into the cytosol.

Trafficking and Targeting to a Specific Membrane

Proteins that contain one or more transmembrane domains obviously do not require lipid modification to promote membrane binding. Rather, attachment of lipophilic groups has been shown to regulate their intracellular trafficking. Palmitoylation of G-protein-coupled receptors (GPCRs) is required for efficient delivery of these seven-transmembrane proteins to the cell surface. Nonpalmitoylated GPCRs accumulate in intracellular membranes resulting in decreased localization at the plasma membrane. For other types of receptors, for example, the AMPA receptor, palmitoylation has the opposite effect. When coexpressed with its cognate PAT (DHHC3/GODZ), the GluR subunits of the AMPA receptor are palmitoylated and retained in the Golgi, and cell-surface expression is reduced.

Proteins that are modified with either myristate or farnesyl alone have weak affinities for membranes and are randomly distributed throughout the cell. These mono-lipidated proteins are found in the cytosol as well as nonspecifically associated

with intracellular membranes. Further modification with palmitate can have a dramatic effect on protein targeting and subcellular localization. This concept is best illustrated by pioneering studies from the laboratories of Bastiens and Kenworthy on H-Ras and N-Ras proteins. These Ras proteins transit from their site of synthesis in the cytoplasm to the plasma membrane via vesicular trafficking mediated by the secretory pathway. H-Ras and N-Ras are first farnesylated in the cytosol, and then bind to the ER, where the CAAX box is further modified. Vesicular trafficking brings the proteins to the Golgi, where they are palmitoylated by a complex containing the DHHC9 PAT, and then delivers farnesylated, palmitoylated Ras proteins to the plasma membrane. Depalmitoylation at the plasma membrane occurs rapidly and results in release of Ras into the cytosol. Farnesylated (nonpalmitoylated) Ras is initially distributed randomly throughout the cell, but ultimately is concentrated or trapped at the Golgi as it becomes palmitoylated by its Golgi-associated PAT. Thus, the membrane containing the modifying PAT specifies the localization of the newly palmitoylated protein, a phenomenon known as 'kinetic bilayer trapping'. If palmitoylation is inhibited by addition of 2-bromopalmitate, or if depalmitoylation is blocked by attachment of a noncleavage palmitate analog to Ras, then Ras becomes mislocalized to all internal membranes.

There are now multiple examples of proteins that undergo reversible shuttling between the plasma membrane and the nucleus in a palmitoylation-dependent manner. RGS7 is a plasma-membrane-associated protein that regulates G-protein signaling. RGS7 location is regulated by binding to R7BP, a palmitoylated protein. Upon depalmitoylation of R7BP, the RGS7:R7BP complex is released from the plasma membrane and translocates into the nucleus. A polybasic sequence within R7BP functions as a nuclear localization signal (NLS). Likewise, Wrch-1, a Cdc42-like GTPase, contains a C-terminal polybasic region that also contains palmitoylation sites. Translocation of Wrch-1 between plasma membrane and nucleus is regulated by palmitoylation and depalmitoylation reactions.

The ultimate location and fate of a protein may be determined by competition between lipid modification and another signal or posttranslational modification. Here are three examples of reactions that compete with palmitoylation: (1) as described above, when a palmitoylation site lies in close proximity to an NLS, attachment of palmitate may mask the NLS and prevent access to nuclear import receptors; (2) for the yeast SNARE protein Tlg 1 and anthrax toxin receptors, palmitoylation protects the protein from ubiquitination and degradation; and (3) GPCRs have palmitoylation sites close to the phosphorylation sites that regulate receptor desensitization. Palmitoylation reduces receptor phosphorylation. In all three instances, depalmitoylation exposes an additional signal (NLS) or site (ubiquitination or phosphorylation), thereby mediating an alternate fate for the delipidated protein.

Targeting to Membrane Rafts and Other Specialized Membrane Regions

Membrane rafts are small subdomains of the plasma membrane that are enriched in cholesterol and sphingolipids. The lipids in rafts predominantly contain saturated fatty acid chains, which promote tight packing and formation of a

specialized region of the membrane bilayer known as a 'liquid-ordered' domain. Proteins modified by GPI-anchors or saturated fatty acids preferentially localize to rafts. The saturated nature of the fatty acid chain is an important factor in promoting raft association; replacement with a *cis*-unsaturated fatty acid results in displacement of the modified protein from rafts. Myristoylated and palmitoylated proteins localize to the cytoplasmic side of plasma membrane rafts, while GPI-anchored proteins are sorted into raft domains in the *trans*-Golgi network and then trafficked to the exoplasmic leaflet of the plasma membrane. Raft localization of these proteins enhances protein-protein interactions and is important for propagating efficient signal transduction by growth factor and immune cell receptors.

Lipid modification can also serve to direct proteins to other types of distinct membrane subdomains. In polarized cells such as epithelial cells, the plasma membrane is divided into two distinct domains – apical and basolateral – that differ in protein and lipid composition. The GPI-anchor provides a sorting signal that directs the modified protein to the apical surface in most epithelial cells. Palmitoylation has also been shown to regulate protein sorting within membranes. For example, attachment of palmitate dictates targeting to the axons or to the postsynaptic density in neurons, to the myelin membrane in oligodendrocytes, or to tight junctions in epithelial cells.

Inhibition of Lipid Modification: Clinical Implications

The importance of lipid modification for correct protein localization and function has led to development of inhibitors that specifically block attachment of individual hydrophobic groups. Compounds that interfere with N-myristoylation (2-hydroxymyristate) or palmitoylation (2-bromopalmitate) have been widely used in the laboratory to inhibit signal-transduction pathways dependent on fatty acylated proteins. A number of disease states are regulated by lipid-modified proteins, and drugs that inhibit lipid modification are currently in use in the clinic or are in the pipeline. For example, fungal infections are being combated with NMT inhibitors. The substrate-binding properties of fungal NMT are sufficiently different from human NMT to allow development of inhibitors that function as antifungal agents. There is great clinical interest in prenylation inhibitors (farnesyl transferase inhibitors (FTIs) and geranylgeranyl transferase inhibitors (GGTIs)), which are designed to inhibit prenylation of Ras and oncogenic forms of Rho and reduce the growth of Ras-induced human tumors. FTIs have also been shown to prevent cardiovascular disease in a mouse model of progeria, a premature aging syndrome that is driven by abnormal processing of farnesylated lamin A.

Glossary

Caveolae 50–100 nm plasma membrane pits coated with tightly packed oligomers of caveolin-1 and/or other caveolin proteins.

Ganglioside Acidic glycosphingolipid containing one or more sialic acid moieties.

Glycosphingolipid Sphingolipid with one or more sugars as a head group.

GPI-anchored protein Protein anchored on the outside of the plasma membrane by covalent linkage to glycosyl phosphatidylinositol.

Lipid raft Membrane microdomain in the liquid-ordered (l_o) phase; in cell membranes, rich in sterol and sphingolipids.

Sphingolipid Membrane lipid with a ceramide backbone consisting of a sphingoid base backbone and a long saturated acyl chain, and a polar head group.

Introduction

Lipids do not always mix uniformly in membranes, but can cluster to form microdomains. A certain class of these microdomains has been termed 'lipid rafts'. These are enriched in cholesterol and sphingolipids. Rafts probably exist in membranes in the liquid-ordered phase or a phase with similar properties. Increasing evidence suggests that phospholipid-rich liquid-crystalline phase domains and sphingolipid-rich liquid-ordered phase domains (rafts) can exist in equilibrium in biological membranes, especially the plasma membrane. Preferential partitioning of membrane proteins into rafts can affect function. Among the proteins that are targeted to rafts are those anchored in the outer leaflet of the membrane through covalent attachment to a special glycolipid, glycosyl phosphatidylinositol (GPI). Other proteins that are linked to saturated acyl chains, such as those that are directly acylated with two or more palmitate chains, or a palmitate and a myristate chain, are also targeted to rafts. Targeting of GPI-anchored proteins and other proteins to rafts plays a role in signal transduction, especially in hematopoietic cells, and possibly also in sorting in intracellular membranes and regulation of cell-surface proteolysis in other mammalian cells.

Physical Properties

The fact that membrane lipids have such heterogeneous structures suggests that they may mix nonrandomly in the bilayer to form lipid microdomains. However, despite much interest in the subject, good evidence that lipids cluster in cell membranes has been slow to emerge. We will discuss one type of microdomain that has recently been described in cell membranes. These are rich in cholesterol and sphingolipids, and probably exist in membranes in the liquid-ordered (l_o) phase or a phase with similar properties. These domains have also been called rafts. The fact that rafts are in the l_o phase gives them a surprising but technically useful property; they are resistant to solubilization by nonionic detergents such as Triton X-100 in the cold. Thus, after extraction of cells in detergent, insoluble rafts can be separated from fully solubilized nonraft proteins and lipids, and isolated for further analysis. We will use the

term 'raft' to refer to the domain in the intact membrane, and the term 'detergent-resistant membrane' (DRM) to refer to the structure isolated by detergent insolubility.

Certain proteins, including those anchored in the membrane by GPI and those linked to dual saturated acyl chains such as palmitate and myristate, are targeted to rafts. We discuss GPI-anchorage, an unusual form of membrane anchorage, in detail, covering synthesis and the types of proteins that are GPI-anchored. We also discuss the functions of GPI-anchorage, focusing on the ability of this modification to target proteins to lipid rafts (Figure 1).

Lipid-Phase Behavior

Since rafts are probably in a separate phase from the rest of the bilayer, we briefly review membrane lipid-phase behavior. Artificial bilayers consisting of one pure phospholipid species exist in a frozen, ordered, gel phase at low temperatures. Acyl chains of gel-phase lipids are extended and packed tightly together, and lipids have low rates of rotational mobility and diffusion in the bilayer. These frozen acyl chains have a melting temperature (T_m) that is characteristic of each phospholipid species. Above this temperature, the bilayer is present in a phase, termed 'liquid-crystalline (l_c)' or 'liquid-disordered (l_d)', in which the lipid acyl chains are fluid and disordered. In the l_c phase, the acyl chains are disordered and do not pack tightly together. They also have high rates of rotational and lateral mobility in the bilayer. Binary mixtures of phospholipids with different T_m can be examined at temperatures between the T_m of the two lipids. When one component is present at low levels, the mixture is uniform, and generally remains in the phase favored by the major component. Above a threshold concentration of one component, cooperative phase separation occurs, and gel and l_c phase domains can coexist. In these two-phase systems, the gel phase is enriched in the high- T_m lipid, and the l_c phase is enriched in the low- T_m lipid. Phase separation in these mixtures is affected by temperature; high temperatures favor the l_c phase, while low temperatures favor the gel phase. Whenever two phases are present, the lipid composition of each phase remains constant. Thus, as the lipid composition and the temperature are changed, only the

Figure 1 Diagram of a membrane raft. Rafts form in membranes rich in cholesterol or other sterols (red) and sphingolipids (blue). Rafts are enriched in these lipids, and relatively depleted in phospholipids (black). Most phospholipids in biological membranes contain one unsaturated acyl chain (curvy line). Lipids can form rafts spontaneously in model membranes, though proteins may affect raft formation in cell membranes. Most sphingolipids are present in the outer leaflet of the plasma membrane. The lipid composition of inner leaflet rafts is not known. Proteins with a high affinity for the ordered lipid environment present in rafts can concentrate there. These include GPI-anchored proteins (whose phosphatidyl inositol moieties generally contain two saturated acyl chains), acylated cytoplasmic proteins such as Src-family tyrosine kinases and α subunits of heterotrimeric G proteins, and some acylated transmembrane proteins (which are generally modified with palmitate chains). Saturated acyl chain lipid modifications on proteins are represented by thick red lines.

relative amount of the two different phases in the membrane changes.

Eukaryotic cell membranes contain mixtures of glycerolipids (in mammalian cells, all phospholipids except sphingomyelin), sphingolipids, and sterols. Biological glycerolipids generally have very low T_m , while sphingolipids (especially glycosphingolipids) have much higher T_m . This disparity has suggested that phase separation between glycerolipid- and sphingolipid-rich domains (possibly in the l_c and gel phases, respectively) might occur in membranes in cells. Because lipids in the gel phase are insoluble in detergent, DRMs might be gel-phase domains. However, although phase separation between l_c and gel phases has been well characterized in model membranes, the gel phase does not appear to exist in biological membranes, except in unusual cases. In addition, DRMs are rich in cholesterol, making it unlikely that they are present in the gel phase. However, another type of phase separation has also been described in model membranes. This is phase separation between two fluid phases in binary mixtures of a saturated-chain phospholipid (which has a high T_m) and cholesterol. In this case, above the T_m of the phospholipid, a liquid-ordered (l_o) phase can separate from the l_d phase as

the amount of cholesterol is increased. Acyl chains of lipids in the l_o phase have properties that are intermediate between those of the gel and l_d phases. They are extended, ordered, and tightly packed together, as in the gel phase, but have high lateral mobility in the bilayer, as in the l_d phase. Phase separation between the l_d and l_o phases also occurs in model membranes containing ternary mixtures of high- and low- T_m lipids and cholesterol, although the process is more complex. In particular, l_c/l_d phase separation occurs at 37 °C in mixtures of phospholipids, sphingolipids, and cholesterol in proportions similar to those found in the plasma membrane. This result is important because it shows that the formation of l_o phase domains in the plasma membrane is plausible from a biophysical standpoint.

DRMs Are in the l_o Phase

Several studies suggest that DRMs isolated from cells exist in intact membranes as domains in the l_o phase. First, DRMs are in the l_o phase when they are isolated. Second, controlled experiments have addressed the possibility of detergents

introducing artifacts. One such artifact is that lipids in membranes might be in a uniform phase, with a concentration of sphingolipids (high- T_m lipids) too low to induce phase separation. However, detergent might preferentially extract low- T_m phospholipids first. As phospholipids are gradually removed, the concentration of sphingolipids in the membrane might gradually increase. This process might eventually lead to phase separation when a threshold concentration of sphingolipids is reached. Detergents do not act in this manner, as shown by model membrane experiments. A series of liposomes whose phase behavior is known from methods independent of detergent extraction is made. Some of these liposomes contain sphingolipids and cholesterol, but at levels too low for phase separation. When these liposomes are extracted with detergent, no DRMs are produced. This shows that detergent does not rearrange membrane lipids to induce DRM formation.

Two different models of raft formation have been proposed. The first model, supported by most data, suggests that rafts form by phase separation. Thus, structural features of lipids that affect T_m and promote phase separation will also promote raft formation. One key difference between phospholipids and sphingolipids is the length and saturation of their acyl chains. Lipid head-groups can also contribute to T_m by altering the way lipids pack together. According to our model, acyl chain packing plays a key role in raft formation. Head group interactions might also be important, although these interactions may affect raft formation indirectly by affecting acyl chain packing. Cholesterol is recruited to rafts due to its ability to pack tightly with lipids of high T_m when the l_o phase is formed. Another group has proposed a different model for raft structure. According to the second model, rafts are primarily clusters of glycosphingolipids held together through hydrogen bonding or other interactions between glycosphingolipid head groups. Because cholesterol has a small head group, it is recruited to rafts because it fits well in the gaps between bulky headed glycosphingolipids.

Proteins in DRMs

The physiological significance of raft formation is likely to stem from the preferential partitioning of certain proteins into rafts. It has been known for several years that proteins anchored in membranes by GPI are detergent-insoluble and are present in DRMs. Acylated proteins, which are covalently linked to fatty acids, can also be targeted to DRMs. In both cases, this is likely to occur through partitioning of order-preferring lipid modifications into rafts. Thus, proteins that have an affinity for an ordered lipid phase will partition into rafts.

GPI-anchorage can target proteins to rafts. It has become clear in the last few years that targeting to rafts is an essentially universal property of GPI-anchored proteins in mammalian cells. Proposed function(s) of this targeting, which is still being elucidated, includes sorting in polarized epithelial cells, signal transduction, and regulation of cell-surface hydrolytic activity. GPI-anchored proteins have long been known to be insoluble in nonionic detergents such as Triton X-100 in the cold. The basis of this property was not understood until recently. Integral membrane proteins are generally detergent soluble

unless they are linked to cytoskeleton. However, GPI-anchored proteins do not have access to cytoskeleton, as they are located in the outer leaflet of the plasma membrane. Detergent-insoluble GPI-anchored proteins are enriched in DRMs. This finding led us to postulate that partitioning of the saturated acyl chains on GPI-anchored proteins into the l_o phase targets the proteins to rafts. Alternatively, protein-protein contacts might be required for detergent insolubility of GPI-anchored proteins. To test these possibilities, we purified a GPI-anchored protein, placental alkaline phosphatase (PLAP), and incorporated it into sphingolipid/cholesterol-rich liposomes (SCRL) that (as discussed above) probably contain both detergent-soluble l_d and detergent-resistant l_o phase domains. When we incorporated PLAP into these liposomes, subjected them to detergent extraction, and separated DRMs and the Triton-soluble fractions, we found that PLAP was associated with the DRMs. This result shows that the protein interacts directly with lipids in the l_o -phase. Other GPI-anchored proteins behave the same way, while a control transmembrane protein is fully solubilized.

Functions of Rafts

Rafts have been proposed to form in the *trans*-Golgi network, and to function during sorting of apical and basolateral proteins into separate transport vesicles in polarized epithelial cells. In what appears to be an analogous process, rafts have also been implicated in axonal versus dendritic sorting of proteins in neurons. Rafts are required for infection of mammalian cells by a number of viruses, including HIV, measles, and Ebola virus. They are also required for both entry of viruses into target cells and budding of mature virions from infected cells. However, the best-characterized functions of rafts are in signaling, especially in hematopoietic cells, and in membrane pits called caveolae, as described next.

Signaling in Hematopoietic Cells

Signaling through the antigen receptors in both T cells and basophils also occurs in rafts. For instance, in T cells, the T-cell receptor (TCR), associated kinases Lck and Fyn, the downstream adaptor protein LAT, and the costimulatory protein CD28 are present in rafts during signaling. Mutations in Lck and LAT that prevent association of these proteins with rafts affect signaling through the TCR, as do agents that disrupt rafts. These results show that rafts play an important role in signaling in T cells. This novel mechanism of regulating interactions between proteins by selective partitioning into membrane domains is unlikely to be restricted to one cell type. Further work is likely to demonstrate the importance of rafts in signaling in other cell types as well.

Caveolae

Caveolae are 50–100 nm pits in the plasma membrane of most mammalian cells. The membrane protein caveolin-1 plays an important structural role in caveolae, and can induce their formation when expressed in cells that lack caveolae. Unlike

clathrin-coated pits, whose formation is induced by transient recruitment of soluble clathrin and adaptor complex coat to membranes, caveolin-1 is an integral membrane protein, and remains embedded in the membrane. Caveolin-1 (22 kDa) forms high-molecular-weight oligomers (400–600 kDa). These oligomers associate with each other in the plane of the membrane in caveolae. Several pieces of evidence show that lipid rafts are concentrated in caveolae. For instance, GPI-anchored proteins have a high affinity for caveolae and will cluster there when cross-linked by antibodies. Gangliosides, acidic glycosphingolipids that are important components of lipid rafts, show similar behavior. Caveolin-1 itself has a high affinity for rafts, and is enriched in DRMs.

Several functions have been ascribed to caveolae. They appear to be signaling centers, where a number of signaling proteins are concentrated. A role for caveolae in intracellular cholesterol transport has also been proposed. Caveolin-1 is a cholesterol-binding protein, which may contribute to a role in cholesterol homeostasis. Caveolae can also internalize from the cell surface. In endothelial cells, caveolae may participate in transport of albumin across the cell monolayer. At least some pathogens have co-opted this pathway. SV40 virus and some pathogenic *Escherichia coli* bacteria enter mammalian cells through caveolae during infection.

Glossary

Affinity A measure of the strength of binding between two molecules, measured, for example, by radioligand binding. Distinguished from apparent affinity, which is based on measurements of effects rather than chemical binding.

Excised patch A patch clamp configuration for measuring currents through ion channels wherein a glass pipette is used to pull a piece of plasma membrane off a cell, exposing the inner surface of the membrane to the bathing medium.

Förster resonance energy transfer (FRET) The radiationless transfer of energy between two fluorophores that occurs when: (1) the emission spectrum of the donor fluorophore overlaps the excitation spectrum of the acceptor fluorophore and (2) the two fluorophores are in sufficient molecular proximity. Used to assess proximity between two molecules, such as fluorophore-labeled pleckstrin homology domains. Sometimes called fluorescence resonance energy transfer.

Homotetramer A protein complex (such as an ion channel) consisting of four identical subunits. A heterotetramer would consist of four nonidentical subunits.

Inward rectifier A potassium channel type that conducts K^+ ions more readily in the inward direction than in the outward direction.

Ion channel An integral membrane protein (or protein complex) that forms a pore permeable to ions. Ions permeate through ion channels following their electrochemical gradient.

Pleckstrin homology (PH) domain A fold occurring in pleckstrin and several other proteins that, in many cases, binds phosphoinositides such as PIP_2 . In the context of this article, we refer to the PIP_2 -binding PH domain from phospholipase C δ_1 .

Transporter An integral membrane protein that passes ions against their electrochemical gradient by using energy from adenosine triphosphate (ATP) (primary active transport) or from the electrochemical gradient of another ion (secondary active transport). To be distinguished from ion channels, which permit the passive flow of ions along their concentration gradients.

Voltage-sensitive phosphatase A recently discovered integral membrane protein consisting of a voltage sensor linked to a phosphoinositide 5-phosphatase. The phosphatase is activated by membrane depolarization.

Introduction

Membrane lipids have a structural role, forming the fluid-insulating bilayer that supports membrane proteins. In addition, certain minority lipids have informational roles. They turn over constitutively, and in response to stimuli, they regulate activities of many membrane proteins, and they recruit cytoplasmic proteins to the membrane interface. Prominent among the informational lipids are the phosphoinositides.

Diversity and Localization of Phosphoinositides

Phosphoinositides are phospholipids that reside in the cytoplasmic leaflet of the plasma membrane and of organellar membranes. They interact with membrane proteins, including ion channels. Phosphoinositides have the cyclic six-carbon inositol head group linked through phosphoglycerol to two fatty acid tails that extend into the membrane, typically arachidonic acid at the 2-position of glycerol and stearic acid at the 1-position. The inositol ring can be phosphorylated at positions D-3, D-4, and D-5, generating seven phosphorylated phosphoinositide species from bare phosphatidylinositol (PI): singly phosphorylated $PI(3)P$, $PI(4)P$, and $PI(5)P$; doubly phosphorylated $PI(3,4)P_2$, $PI(3,5)P_2$, and $PI(4,5)P_2$; and triply phosphorylated $PI(3,4,5)P_3$. Each phosphoinositide species

is recognized by different proteins. Phosphoinositides are converted from one species to another by lipid kinases and lipid phosphatases. They move between cellular membranes during membrane trafficking and some are transported by phospholipid transfer proteins. Compared to PI, and especially the other kinds of phospholipids of the cell, all polyphosphoinositides have low abundance and relatively fast turnover.

Different cellular membranes have distinct characteristic phosphoinositide species. PI is synthesized in the endoplasmic reticulum; $PI(4)P$ is present in the Golgi complex, secretory vesicles, and probably on the plasma membrane; $PI(4,5)P_2$ and PIP_3 populate the plasma membrane; $PI(3)P$, $PI(3,4)P_2$, and $PI(3,5)P_2$ are present in the endosomal pathway; and several species may be present in the nucleus. These phosphoinositide 'signatures' are maintained by enzyme compartmentalization. The pool of $PI(4,5)P_2$ is tonically present in the plasma membrane, whereas PIP_3 is produced only transiently when PI 3-kinases are activated by receptors.

Phosphoinositides have diverse functions – they are involved in membrane budding and fusion, cytoskeletal dynamics, control of nuclear function, and assembly of signaling proteins at membranes. They also regulate the activity of plasma membrane ion channels and transporters. Phosphoinositides gain all these functions through specific lipid–protein interactions. As $PI(4,5)P_2$ is the best-studied plasma membrane phosphoinositide,

Table 1 Tools and approaches to probe phosphoinositide action on ion channels

Where and how abundant are phosphoinositides?

- Phosphoinositide-binding domains fused to fluorescent proteins can report location and spatiotemporal changes within living cells.
- Biochemical methods (membrane extraction and chromatography) in populations of cells can give absolute amounts of phosphoinositide species (normalized to anionic lipids or protein).
- Ionic current through known PIP₂-sensitive ion channels can report relative changes in PIP₂.

Do changes in phosphoinositide levels affect ion channel activity?

- Add phosphoinositides:
 - Soluble analogs (e.g., short-chain PIP₂) to inside-out membrane patches.
 - Carrier shuttle protein to escort lipid into cell.
- Chelate/sequester phosphoinositides from cytoplasmic side:
 - Polycations (neomycin, polymycin, spermine, and Mg²⁺).
 - Antibodies.
 - Binding proteins (palmitoylated peptides, pleckstrin homology (PH) domains, and MARCKS proteins).
- Stimulate lipid enzymes:
 - Overexpress phosphoinositide kinases or phosphatases.
 - Stimulate upstream receptors or raise Ca²⁺ to activate PLC.
 - Induce membrane targeting of enzymes using dimerization of FKBP–FRB by rapamycin.
 - Express voltage-activated phosphatase (VSP, a PI 5-phosphatase).
- Inhibit lipid enzymes:
 - RNA interference (established for several PI 5-kinase isoforms).
 - Nonhydrolyzable ATP analogs (stops kinases only).
 - Pharmacological blockers (10 μ M phenylarsine oxide for PI4KIII α , 10 μ M wortmannin for PI4KIII α , and β ; several PI3-kinase inhibitors).

What is the affinity of channels for phosphoinositides?

- Concentration–response relationship applying soluble PIP₂ analogs on excised membrane patches.
- Biochemical methods (PIP strips, pull-down assays).

What regions of the channel are important for interaction with phosphoinositides?

- Mutate individual amino acids and test responsiveness or affinity to phosphoinositides.
- Solve ion-channel crystal structure; model interaction with phosphoinositides.
- Determine crystal structure of channel with the lipid.

the further discussion emphasizes this molecule, referred to hereafter as PIP₂. Levels of PIP₂ can be downregulated dynamically by physiological stimulation of receptors that activate PIP₂-selective phospholipase C (PLC).

Ion Channels and Transporters Modulated by Phosphoinositides

Phosphoinositide modulation of membrane proteins has been explored by the methods outlined in Table 1. The experiments have shown that several classes of plasma membrane ion channels are regulated by PIP₂. Most of these channels conduct less current when PIP₂ is depleted, but a few conduct more. So far, the list includes: inward rectifier potassium channels, Kir1 (ROMK), Kir2 (IRK), Kir3 (GIRK), and Kir6 (K_{ATP}); voltage-gated potassium channels, especially Kv7 (KCNQ); voltage-gated calcium channels (Ca_v); most transient receptor potential channels (TRP); the epithelial sodium channel (ENaC); possibly the cystic fibrosis transmembrane conductance regulator; and connexin43. To illustrate with one example: KCNQ K⁺ channels can be turned off more than 90% by activating the enzymes PLC or PIP₂ 5-phosphatase (Figure 1) and by chelating PIP₂ with polycations; the recovery of current after PLC activation is prevented when there is no hydrolyzable adenosine triphosphate (ATP) or when PI 4-kinase is blocked; the recovery is speeded by overexpression of PI 4-kinase or PIP 5-kinase, or by applying soluble forms of PIP₂ to the cytoplasmic face of the membrane.

Figure 1 PIP₂ is required for KCNQ2/3 channel activity. This experiment uses expression of a unique voltage-sensitive phosphatase which is activated by large membrane depolarizations. Activation of the voltage-sensitive 5-phosphatase depletes PIP₂ (as reported by loss of PH domain FRET) and suppresses whole-cell KCNQ current recorded by patch clamp. Current records averaging data from several cells were obtained by the methods of Falkenburger BH, Jensen JB, and Hille B (2010) Kinetics of PIP₂ metabolism and KCNQ2/3 channel regulation studied with a voltage-sensitive phosphatase in living cells. *Journal of General Physiology* 135: 99–114.

Phosphoinositides also regulate transporters and pumps: the sodium/calcium exchanger (NCX); the plasma membrane calcium adenosine triphosphatase (ATPase); and the sodium/proton exchanger. These transporters slow or stop if PIP₂

is depleted. NCX was one of the first membrane proteins for which slowing by PIP₂ depletion was shown. Here, we consider transporters collectively with ion channels for simplicity.

Features of Phosphoinositide Modulation of Ion Channels

PIP₂ Sensitivity and Apparent Affinity

Ion channels differ in their sensitivity to PIP₂. In several channels, the open probability can be increased from virtually zero to almost unity by exposing PIP₂-depleted membranes to high concentrations of soluble PIP₂. The midpoint of this concentration–response curve defines the apparent affinity of the channel for PIP₂. Differences in PIP₂ affinity among channel subtypes are physiologically relevant. At resting levels of PIP₂ in a cell, high-affinity channels will be almost saturated with PIP₂, whereas low-affinity channels will have fewer PIP₂-binding sites occupied. Given similar channel densities, current through the high-affinity channels will be larger. For example, among inward rectifier potassium channels, IRK and ROMK channels are distinguished by their constitutive activity resulting from high affinity for PIP₂. Other inward rectifier channels, such as GIRK, have low resting PIP₂ affinity and low constitutive activity. Activation of these channels requires binding of G-protein $\beta\gamma$ subunits, which increase channel affinity for PIP₂.

High- and low-affinity channels also differ in their response to changes in PIP₂ levels. Low-affinity channels let go of their PIP₂ more easily than high-affinity channels. PIP₂ levels can fall quickly during activation of PLC by receptors and are changed by other physiological stimuli as well. With falling PIP₂ levels, currents through low-affinity channels will drop more quickly and more thoroughly than currents through high-affinity channels. Thus, less PIP₂ depletion is required to inhibit 50% of resting current for low-affinity channels than for high-affinity channels. For example, heterotetrameric KCNQ2 or KCNQ4 channels have a 100-fold lower apparent affinity for PIP₂ than do heterotetrameric KCNQ3 channels, making them much more responsive to PLC-induced PIP₂ depletion. Choosing high-affinity versus low-affinity channels is one way by which cells can tune their responsiveness to PLC-coupled receptors.

With most means of PIP₂ depletion, physiological or experimental, PIP₂ levels do not fall to zero, but to a new lower steady state that balances PIP₂ synthesis and depletion. At this steady state, a substantial proportion of high-affinity channels still might have some PIP₂ bound, so that current inhibition is incomplete. Experimentally, it can be difficult to determine whether residual current in PIP₂-sensitive channels is a function of incomplete PIP₂ depletion or of partial channel function in the absence of PIP₂. Other acidic phospholipids might support partial channel activity.

Interaction with Other Channel Regulators

In many cases, PIP₂ apparently binds directly to the ion channel to activate it, and channel inhibition upon receptor activation is mediated by PIP₂ depletion. But there are examples where the situation is more complex:

Figure 2 Ion-channel-binding sites for PIP₂ and intracellular regulators overlap. For several classes of channels, including KCNQ and TRP, binding sites for intracellular signals such as calmodulin and protein kinase C overlap with putative PIP₂-binding sites in the proximal C terminus. For KCNQ channels, this domain is located between C-terminal helices called A and B (which also coincides the binding site for scaffolding protein AKAP79/150), and for TRP channels it is in the vicinity of the consensus C-terminal TRP box.

1. PIP₂ does not need to bind to the channel itself. For NCX-1, PIP₂ appears to have indirect effects in addition to a known direct interaction with the exchanger. These include regulation via cytoskeletal remodeling and membrane trafficking.
2. PIP₂ changes the affinity of the channel for other regulatory elements. In the cardiac NCX exchanger, PIP₂ increases the affinity of a regulatory binding site for Ca²⁺, thus activating the exchanger. PIP₂ decreases the apparent affinity of K_{ATP} channels for the negative regulator ATP, thereby increasing current. For TRP and KCNQ1 channels, PIP₂ also reduces calmodulin binding, thereby relieving inhibition of current (Figure 2).
3. Other regulatory elements change PIP₂ affinity. Phosphorylation by PKA increases the affinity of ROMK channels for PIP₂, increasing channel activity. Phosphorylation of GIRK channels by PKC lowers their affinity for PIP₂, whereas G-protein $\beta\gamma$ subunits and intracellular Na⁺ increase GIRK channel affinity for PIP₂.

Based on allosteric considerations, examples (2) and (3) should be synonymous. They are described separately to reflect the different experimental approaches used. The interaction between PIP₂ and other channel modulators is not surprising given that channel structures would change upon binding of phosphoinositides and that binding sites for phosphoinositides and other regulators can overlap. In many channels, including KCNQ and TRPV1, this ‘hot spot’ for binding of channel modulators is located in the proximal C-terminus (Figure 2).

Phosphoinositide Specificity in Ion-Channel Regulation

Whether an ion channel is regulated by a particular phosphoinositide depends on several factors. (1) Phosphoinositide availability: PI(4,5)P₂ and PI(4)P each make up 1% of the total anionic phospholipids of the cell. PI(3,4)P₂, PI(3,5)P₂, and PI(3,4,5)P₃ are much less abundant. PI(4,5)P₂ is unique in its reliable presence at the plasma membrane, but many enzymes transiently change the density of PI(4,5)P₂, making it a dynamic signaling molecule. These features make PI(4,5)P₂ the most physiologically relevant phosphoinositide regulator of ion channels at the plasma membrane. (2) Charge: In channels as in other phosphoinositide-binding proteins, several

(three or more) basic amino acid residues close to the plasma membrane interface are thought to interact electrostatically with the acidic phosphate groups of phosphoinositide head groups. A doubly phosphorylated phosphoinositide will bind more strongly than a monophosphorylated one. (The phosphoinositide-interacting residues need not be adjacent in the sequence of the protein.) (3) Structure of the ion-channel phosphoinositide-binding site: The specificity of phosphoinositide-binding domains in various proteins ranges from highly selective (PH, PX, and FYVE domains) to promiscuous (MARCKS proteins). Proteins with a structured binding pocket even can discriminate between isomers, for example, PI(4,5)P₂ versus PI(3,4)P₂; others are less selective. ENaC channels are stimulated by PI(4,5)P₂, PI(3,4)P₂, and PI(3,4,5)P₃, but appear to bind PIP₂ and PIP₃ at distinct sites. IP₃ receptors are also sensitive to PIP₂, and the activity of TRPV1 can be supported by PIP, PIP₂, and PIP₃. For proteins with a less-structured interaction, some functional specificity may be achieved by co-localization with kinases and/or phosphatases that generate a microdomain with a specific phosphoinositide population (specificity by abundance, see above).

Some ion channels present a bimodal sensitivity to phosphoinositides. In a heterologous system, current through some Ca_v channels is stimulated by low PIP₂ and depressed by high PIP₂ levels. The effects of low PIP₂ do not change voltage dependence of gating, whereas those of high PIP₂ shift the voltage dependence of opening to more positive potentials. The latter shift is similar to the willing/reluctant paradigm of modulation of Ca_v by G-protein βγ subunits. It is postulated that these channels contain two binding sites for PIP₂, one of lower and one of higher affinity, a mechanism also suggested for TRPV1.

Structural View of Ion-Channel Modulation

Voltage-gated potassium and TRP channels are formed by four homologous subunits. Each subunit has an N-terminal voltage-sensor domain, a pore domain, and a C-terminal tail. Most evidence suggests that PIP₂ interacts with residues in the proximal C-terminus (Figure 2). The phosphoinositide specificity of ion channels provides a clue to the structure of their phosphoinositide-sensitive domains, with promiscuous channels employing a cloud of charges and more discriminating channels using a better defined binding pocket analogous to PH domains. However, some members of the TRP family of ion

channels (e.g., TRPM4) may employ both motifs. In no case is the structure of a putative-binding pocket actually known.

Conclusions

An accumulating body of work demonstrates that many plasma membrane proteins – ion channels and transporters – require PIP₂ to function. Changing PIP₂ levels over time allows for temporal modulation of these channels, for instance by G_q-coupled receptors. Different phosphoinositide compositions of cellular membrane compartments potentially allow for spatial regulation of channel function, determining where ion channels work, and where they do not. A similar phosphoinositide regulation may be found in the future for other classes of membrane proteins and for intracellular membranes in addition to the plasma membrane.

Live Cell Imaging of Nuclear Dynamics

J C Harr and K L Reddy, Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2013 Elsevier Inc. All rights reserved.

The search for the mechanisms underlying nonrandom chromosome and gene organization within the nuclear volume and the precise functional consequences of such a configuration lies at the heart of research into nuclear dynamics. It has been demonstrated that chromatin is likely organized into discrete domains by association with distinct nuclear compartments enriched in structural and regulatory proteins. Growing evidence suggests that gene activity is modulated by interactions with these subnuclear compartments and that such interactions can be cell type specific. Analyzing how nuclear architecture controls genome activity and the mechanisms that drive such organization is necessary to fully understand complex biological processes such as development and disease. The most widely used approaches in understanding and illuminating nonrandom organization of the genome have relied on high-resolution two- or three-dimensional fluorescent *in situ* hybridization (FISH) techniques at the single cell level and on bulk cell population analyses using molecular methods such as chromosome conformation capture (3C and its derivatives such as Hi-C) and DNA adenine methylation identification (Dam-ID) which measure probabilities of chromosomal regions interacting with each other or with a nuclear domain, respectively. While these powerful molecular and high-resolution microscopy techniques have given us a wealth of understanding about nuclear architecture, they reflect an average of a bulk population and are necessarily static. Complementary live cell imaging techniques using the living cell as both a visual and molecular test tube are vital to our understanding of the dynamics and mechanisms underlying nuclear organization. The most insight will be gained by studies using genome wide studies of nuclear architecture, such as Dam-ID and Hi-C, that illuminate frequencies or averages of nuclear structure in a cell population, coupled with live cell studies that capture real-time spatial dynamics of nuclear positioning and molecular consequences of nuclear compartmentalization.

The Dynamically Organized Nucleus

The mammalian nucleus has a complex structural organization that dynamically interacts with the genome. Chromatin is organized into discrete domains by association with distinct nuclear compartments that are defined by their enrichment in structural and regulatory proteins. Growing evidence suggests that gene activity is modulated by interactions with these subnuclear compartments. Such compartmentalization has been proposed to bring together genes whose transcription or repression is coordinately regulated. Recent evidence suggests that the nonrandom organization of chromosomes in the nucleus is a contributing factor in facilitating specific translocations and that disruption of normal nuclear architecture leads to a variety of diseases including premature aging, Burkitt's lymphoma, some types of muscular dystrophy, and other so-called laminopathies.

However, while mounting evidence suggests that gene activity is regulated by nuclear compartmentalization, relatively little is known about how specific loci are directed to or associated with different nuclear domains. Additionally, the molecular consequences of such organization are unknown. In fact, most of the studies to date have relied on cytological analysis of fixed specimens and are, thus, correlative. By contrast, live cell methodologies that direct compartmentalization allow one to discriminate between positioning and molecular consequence. The consequences of such directed re-positioning or compartment formation on gene activity or other DNA transactions (e.g., replication timing) can then be analyzed by molecular or fixed cell approaches. In addition, other live cell technologies that detect protein–protein interactions, such as bi-molecular fluorescence complementation (BiFC), and those that detect nascent RNA production (e.g., through MS2-hairpin recognition) in combination with the directed compartmentalization techniques allow the living cell to give both 3D/4D position and quantifiable molecular data.

3D-FISH and Genome Wide Molecular Approaches: Insights into Nuclear Architecture

Three different technologies have been widely used to analyze and study nuclear architecture and dynamics: 3D-FISH, chromosome conformation capture or 3C (more recently its derivatives, ChIA-PET and Hi-C), and Dam-ID. In all of these techniques, the assays are designed to reflect and probe for nuclear architecture and therefore are either performed on fixed (FISH and Hi-C) or initiated in live cells (Dam-ID). As such, the Dam-ID and Hi-C techniques represent a great step forward from canonical molecular assays which disregard three-dimensional context. 3D-FISH analyses give greater insight into position and colocalization with protein compartments than its ancestors 2D-FISH and simple immunofluorescence detection of proteins.

Fluorescence *in situ* hybridization on three-dimensionally preserved nuclei (3D-FISH) has become a major tool to study higher-order chromatin architecture in the interphase nucleus. Even with the development of live cell imaging assays, this technique will remain a powerful tool since it can be used on virtually any cell or tissue type. The 3D-FISH technique involves hybridization of labeled DNA probes to three-dimensionally preserved nuclei to detect single genes, chromosomal domains, or entire chromosome territories. Unfortunately, 3D-FISH requires harsh pretreatments, including a denaturation step, for the best accessibility and hybridization of probes to nuclear target DNA. Light microscopy observations of individual ~1-Mb chromatin domains in the same cells *in vivo*, after fixation, and after 3D-FISH demonstrate that number, size, and spatial distribution of ~1-Mb chromatin domains are generally well preserved throughout the 3D-FISH procedure. In addition,

other studies indicate that both the position of DNA segments and the localization of specific nuclear structures (e.g., promyelocytic leukemia (PML) bodies, nucleoli, and centromere regions of interphase chromosomes) do not change significantly at the light microscopy level even after 3D-FISH treatments. Importantly, regardless of minor perturbations in nuclear structure due to technical issues, 3D-FISH analyses have demonstrated that repositioning of genes and chromosomal domains does occur and that this rearrangement coincides with molecular events, such as transcription of the gene being studied. Such studies have been done on regions to demonstrate proximity to either other chromosomal domains (such as chromosome territories or coordinately regulated loci) or nuclear compartments (such as the nuclear lamina, the nucleolus, transcription factories, PML bodies, splicing factories, etc.). For example, it has been shown that germ-line immunoglobulin heavy chain loci are preferentially localized to the nuclear lamina in hematopoietic progenitors, T lineage cells, and non-B cells (such as fibroblasts) but centrally positioned in the nucleus in pro-B cells, where they are active. Similar repositioning has been shown for the IgK locus, the TCR loci, Ikaros and the cystic fibrosis gene, CFTR, among others. This cytological demonstration of repositioning, while correlative, indicates the dynamics of nuclear architecture in a cell-type-specific manner and hints at a role for nuclear structure in regulation of gene activity. Lacking in these types of assays are real time associations and demonstration of any molecular interactions with, or functional consequences of, association with a given nuclear compartment, or with other loci.

In contrast to 3D-FISH, Dam-ID uses the living cell to mark regions that are in molecular contact with protein components. In this protocol, DNA adenine methyltransferase (Dam) from *Escherichia coli* is fused to a DNA-interacting protein. Dam adds methyl groups to adenines in the vicinity of the fusion protein, thereby marking the interaction site on the underlying DNA segment. This fusion protein is expressed at extremely low levels to ensure no 'off-target' effects. Since higher eukaryotes do not normally have methylated adenines, any marked adenine can be presumed to be a consequence of the fusion protein interacting at the marked site. Moreover, mammalian nuclei appear to be blind to this mark as there is no mechanism for 'reading' adenine methylation. This technique is uniquely suitable for those proteins which are difficult to subject to chromatin immunoprecipitation (ChIP), notably proteins of the inner nuclear membrane INM/lamina or other nuclear compartments. Once the protein is introduced into cells via viral transduction, DNA is isolated and subjected to restriction digestion followed by ligation-mediated polymerase chain reaction (PCR) to amplify regions demarcated by the fusion protein. This DNA can then be analyzed by qPCR to specific genic regions, subjected to hybridization to tiled arrays or, theoretically, high-throughput sequencing. Dam-ID has emerged as a powerful tool to map the interaction of chromosomal segments with INM/lamina proteins, the so-called lamin associated domains or LADs. It should be noted that 3D-FISH analyses hinted at the importance and widespread interaction of some chromosomal domains with the INM/lamina, but the FISH technique is ill-suited to give genome-wide high-resolution maps of association and incapable of indicating

true molecular interactions between chromatin and protein components of a subnuclear compartment. In human fibroblasts, the Dam-ID technique has revealed large (0.1–10 Mb) delimited chromosomal regions which contain mostly inactive chromatin. Many of these domains contain developmentally regulated genes that change their association with this compartment in a developmentally regulated manner. However, it remains unclear how this architecture might functionally contribute to the repression of lineage specific genes and how nuclear organization might vary in other lineages. Thus, Dam-ID is capable of marking chromatin that is associated with a specific nuclear compartment in living cells to give high-resolution maps of chromatin domains. The limitation of this technique is, of course, that the demarcated domains represent an analysis of a bulk population of cells and the dynamics of association are completely obscured since the methyl mark deposited by the methyltransferase is permanent. In addition, since the Dam-ID technique reflects frequencies of association, 3D-FISH analyses are routinely used to verify that a given region is indeed associated with the domain being assayed in a majority of cells.

Like 3D-FISH, the chromosome conformation capture (3C) technique and its derivatives depend upon preserving nuclear architecture by fixation with formaldehyde. In 3C this fixation step is followed by restriction enzyme digestion to leave cross-linked sequences attached. The DNA is then ligated under dilute conditions to favor self-ligation of cross-linked DNA fragments. The ligated fragments, that should contain both pieces of interacting DNA, are then analyzed by PCR with specific primers to the two loci of interest. In this case, one must have an idea of the two interacting regions. While useful for specific loci of interest, 3C has very limited throughput. There have been many variations on this technique, but two have proved to be especially useful in looking at nuclear structure: ChIA-PET (chromatin interaction analysis by paired-end tag sequencing) and Hi-C. The ChIA-PET method combines ChIP-based methods and 3C. Specifically, after fixation, chromatin is sonicated and an immunoprecipitation is performed to a specific protein to enrich for chromatin associated with this protein of interest. After precipitation, two differentially bar-coded linkers are ligated to the sheared ends of the chromatin and then ligated under dilute conditions (as in 3C). After digestion with a restriction endonuclease which cuts outside of the linkers, the resulting complexes are subjected to reverse cross-linking, purification, and high-throughput sequencing. The results give a genome-wide interaction map of *cis*- and *trans*-DNA sequences that are associated with one another through their association with the protein of interest. Hi-C which was designed to detect all pairwise physical associations of DNA in the genome is perhaps the ultimate extension of the chromosome conformation capture (3C) assay. As in 3C and its variants, the cross-linked genome is enzyme-digested and the resulting pieces of genomic DNA are ligated to each other based on proximity. Thus, linear linkages along the chromosomes are virtually erased, and new connections are generated based on three-dimensional proximity within the nucleus. In this case, isolation of pairwise interactions is achieved by incorporating biotin into the ends of the digested DNA before ligation, and then carrying out physical selection of these fragments on streptavidin beads followed by

paired-end sequencing. Like ChIA-PET, this technique gives both *cis*- and *trans*-DNA sequence interactions. However, unlike ChIA-PET, the technique is not constrained (or enhanced, depending upon your point of view) by choosing a particular protein of interest. Both ChIA-PET and Hi-C generate massive amounts of genome-wide data and require very stringent controls to ensure that meaningful interactions are uncovered. Intriguingly, even though these techniques are relatively new, both Hi-C and ChIA-PET techniques have pointed to CTCF-binding sites as regions important for genome organization. Hi-C has demonstrated that active regions and inactive regions of the genome segregate from one another. Again, the pitfalls of these expensive technologies are that they represent a bulk analysis of the chromosomal interactome and are also unable to uncover dynamic molecular processes involved in the organization they uncover.

Insights into Chromosome Dynamics Using Live Cells: The *LacO* System

The LacI/*lacO* system has been widely used in mammalian cells to study chromosomal dynamics and chromatin decondensation. These arrays can and have been used to visualize a chromosomal domain and its movements in living cells under many conditions (Figure 1). Previous studies have demonstrated that LacI binds to *lacO* sites with high affinity ($K_d = 10^{-10}$) and DNA binding is reversed upon incubation with the allosteric inhibitor isopropyl β -D-1-thiogalactopyranoside (IPTG). Importantly, in mammalian cells a fluorescently tagged LacI protein is able to bind to integrated *LacO* sites (256 copies) specifically and can be visualized using simple live cell microscopy techniques. Thus, this system provides for highly specific and stable DNA binding that is reversible using a relatively inexpensive reagent (IPTG). One could also use iterated *tetO*

sequences and tetR fusion proteins in a similar manner with doxycycline to control binding. These artificially designed chromosomal domains have been used to demonstrate *in vivo* dynamics of large amplified arrays of *lacO* binding sites occupying megabases of DNA as well as more discrete regions comprising only one or two sites of integration (10 kb). These integrated arrays have been demonstrated to exhibit simple Brownian motion in interphase nuclei and the larger (Mb) sized integrations, are quite often condensed and heterochromatic. Upon binding of a transcriptional activator to these large designer chromosomal domains, the decondensation of the domain is dramatic and easily seen by light microscopy. In addition, a random integration positioned reproducibly at the nuclear periphery shows dramatic relocalization to the nuclear interior upon trans-activation along with rapid and apparently directed movements. Finally, the extent of movement of individual tagged chromosomal domains varies depending upon their nuclear environment; specifically, chromosomal domains located at the nuclear periphery or chromocenters move in a smaller diameter than those regions located in the nuclear interior. Taken together, such studies demonstrate the utility of using tagged chromosomal domains in living cells to study the interplay of chromosome dynamics and gene regulation in space and time.

Forced Repositioning of Chromosomal Domains Using Molecular Tethers in Living Cells: Insights into Consequences of Repositioning

More recently, the *lacO* system has been used to position integrated test genes to the inner nuclear membrane and to test the consequences of such repositioning on gene activity (Figure 2). Three studies took advantage of targeting strategies

Figure 1 Stably integrated arrays of *lacO* binding sites are visible upon binding of GFP-LacI in living cells. Shown are cells containing the *lacO* repeats that are also expressing GFP-LacI. This interaction is controlled by the allosteric inhibitor IPTG. IPTG can be used in the culture medium to prevent GFP-LacI from binding (+IPTG). Upon IPTG withdrawal (–IPTG), accumulation of the GFP-LacI protein on the *lacO* arrays occurs in a matter of hours. This system has been widely used to look at chromosomal domain dynamics (several megabases) with large amplified regions of *lacO* repeats or dynamics of smaller regions (~10 kb) using single integrations.

Figure 2 Three different strategies expanded upon the original *lacO*/LacI system to tether chromosomal domains to the INM/Lamina. The top two panels demonstrate similar strategies using an INM protein. In the topmost panel, a truncated version of Emerin, Δ EMD, fused to LacI was used to reversibly interact with chromosomal domains. In the middle panel, the INM protein Lap2 β was used as the molecular tether to recruit *lacO* sites. In both cases binding was able to be controlled by introducing the allosteric inhibitor IPTG. In the bottom panel, a cumate inducible LaminB1-LacI fusion was used to recruit *lacO* insertions to the nuclear lamina. The findings from each of the studies are outlined to the right.

using *lacO* sites positioned either well upstream or downstream of a test gene to avoid inhibition of transcription due to binding of LacI fusion proteins. These target constructs (containing *lacO* repeats) were then tethered to the INM/lamina using either a portion of the resident INM proteins (Emerin or Lap2 β) or the nuclear lamina protein LaminB1. These studies focused on recruitment to the nuclear periphery because it is one of the few stable structures in the nucleus (i.e., it has defined location, molecular make-up, and boundaries) and it has been directly implicated in regulating gene activity, specifically gene repression. Other compartments within the nucleus, such as splicing factories, cajal bodies, can occupy any position within the nuclear volume making it more difficult to tease apart recruitment or *de novo* compartment formation that may occur by simply recruiting a high local concentration of regulatory proteins. In both studies using INM protein domains, the chimeric proteins were stably expressed in cells and they resulted in the recruitment of the target *lacO* containing chromosomal domains to the INM upon removal of IPTG. In the case of the LaminB1-LacI chimeric fusion, the protein itself was inducibly expressed and was not regulated by IPTG. In all cases, the *lacO* insertions were reproducibly recruited to the nuclear periphery, allowing, for the first time, a study of the consequences of forced compartmentalization. The two studies utilizing INM proteins (Emerin and Lap2 β) as tethers resulted in transcriptional repression accompanied by changes in chromatin status

around the recruited domain. Intriguingly, the study using LaminB1 focused on the kinetics of gene induction of a reporter gene tethered to the nuclear lamina. The activity of this reporter gene, encoding the cyan fluorescent protein (CFP) and containing MS2-RNA repeats in the intron of the nascent RNA which can be recognized by MS2-YFP protein, allows for visualization of gene activity in individual live nuclei. For this reporter system activity levels were measured by either CFP fluorescence or MS2-YFP accumulation at sites of nascent transcription. Intriguingly, these forced tethering studies also uncovered a potential link between progression through the cell cycle and recruitment to the nuclear lamina. These observations would never have been made using molecular or fixed cell approaches. These adaptations of the original LacI/*lacO* system demonstrate the versatility of using live cell systems to discover not only dynamics of nuclear architecture but also consequences of nonrandom association with a nuclear compartment.

The Future: Induced Repositioning of Chromosomal Domains Using 'Nuclear Zipcodes' or Specific *trans*-Factors Identified by Genome-Wide/Molecular Analyses

How is the architecture of a nucleus set up? This is one of the big questions in the field of nuclear dynamics. The studies

Figure 3 Newer uses of the lacO/LacI system. (a) A new system has been designed to allow for integration of 'nuclear zip codes' into a specific genomic site. This is accomplished by flipping the sequence of interest into an engineered chromosome region containing inverted loxP sites adjacent to *lacO* sequences. In the absence of a sequence that is able to direct compartmentalization, the array is located in the nuclear interior (nucleus at top). After introducing a targeting sequence containing a putative nuclear zip code, the array is now preferentially located at the nuclear periphery (nucleus at the bottom of panel (a)). Analyses using BiFC (see below) or expression from a test gene can be incorporated into this system to garner positional, molecular, and regulatory information. (b) Design of a system to detect molecular interaction of a genomic region with a nuclear compartment. The basic concept of BiFC is illustrated in the box in panel (b). LacI is fused to one-half of fluorescent YFP and a protein located in a nuclear subcompartment is fused to the cognate half of the YFP molecule. If the two proteins are in molecular proximity, a complete fluorescent YFP will be formed. A nuclear zip code is used (as in (a)) to direct a sequence to a subnuclear domain. The LacI fusion protein bound to the *lacO* repeats will be directed to the compartment and will be brought into proximity to allow for formation of the fluorescent protein. This type of analysis allows one to get specific real time information about molecular interactions.

detailed above describe artificial systems where genic regions are ‘forced’ to associate with a nuclear domain by molecular tethers, specifically the INM/nuclear lamina and, thus, did not address this basic question. As mentioned above, the nuclear periphery is one of the few stable structures in the nucleus. In addition, Dam-ID studies have indicated sequences that are in high-frequency association with this domain. Thus, the preferential association of a genomic region with this structure affords the unique opportunity to uncover the role that specific *cis*-elements have in determining genome organization. By definition, such *cis*-elements or nuclear ‘zipcodes’, would direct or facilitate association of chromosomal domains with a specific nuclear compartment. Of course, this concept of nuclear addressing also requires the action of specific *trans*-acting factors that interact with the *cis*-elements to mediate their association within a specific nuclear compartment. For example, the nuclear periphery of mammalian cells is made up by the nuclear lamina (such as Lamin A and B) and the INM, which contains many specific proteins implicated in gene regulation, such as emerin, and Lap2 β .

Using data generated by Dam-ID or ChIA-PET/Hi-C, potential *cis*-elements can be tested for their ability to direct nuclear compartmentalization. The advantage of using such a system is that the *cis*-elements tested would be subject to the normal cell cycle and other cellular controls involved in establishing nuclear architecture – a feature missing from the forced association studies using molecular tethers described above. One can imagine two ways to test the ability of *cis*-elements to reposition an ectopic site to a new position in the nuclear volume in living cells. First, one could simply randomly integrate these elements with *lacO* sites and assay the frequency of association with a given compartment (e.g., the nuclear lamina) by looking at GFP-LacI foci by light microscopy. Unfortunately, such an approach yields multiple integrations and different sites for each different sequence tested, making any conclusions about repositioning suspectable. Moreover, since there is no control over where the insertions take place, analyzing that the consequences of repositioning would not be possible. A better strategy would employ a system that allowed for directed insertion of the *cis* sequences to be tested into the same chromosomal location. An example of a modification of such a system that has been demonstrated to work in this way is shown in [Figure 3](#). This tagged chromosomal insertion site (TCIS) system incorporates the ability to tag a chromosomal region via the *lacO*/LacI system and to recombine specific sequences into the same location using recombination-mediated cassette exchange (RMCE), a well-documented method for site-specific integration of DNA sequences. The engineered chromosomal insertion is comprised of 256 *lacO* sites with an adjacent pair of inverted loxP sites which support recombination of specific sequences into this site. This engineered locus can be followed by introduction of GFP-LacI, which binds to the iterated *lacO* sites and accumulates to generate a discrete focus marking the insertion site. Specific sequences, in a switch cassette, can then be introduced via Cre recombinase to this locus and the disposition of the chromosomal domain within the nucleus can be followed in living cells. Thus, the TCIS system represents a rapid way to assay *cis*-elements for nuclear disposition and activity. Moreover, since the multiple sequences are tested

within the same nuclear environment, artifactual results due to position effects are avoided.

In addition to using live cells to study the mechanism by which *cis*- or *trans*-elements are able or sufficient to cause a chromosomal domain to reposition to a new nuclear domain, live cells can also be used to detect the molecular association of engineered chromosomes with a protein present in a nuclear compartment. BiFC allows the direct visualization of protein complexes in their native environment. BiFC is based on the formation of a fluorescent protein from two nonfluorescent constituents. Specifically, BiFC employs a strategy that splits either GFP or YFP into two domains (an N- and a C- terminal portion) that can complement one another to form a fluorescent protein, but individually have no fluorescence. The two domains only fluoresce when they are brought into close molecular proximity to one another, for example, when they are fused to two proteins that interact with one another ([Figure 3](#)). Coupling this technology with the *lacO*/LacI system should enable detection of such nuclear events as chromosome looping and compartmentalization by fusing one-half of the BiFC to LacI and the other half to either a chromatin interacting protein or a protein resident in a specific nuclear compartment, for example, the nuclear lamina ([Figure 3](#)). BiFC has been used quite successfully to demonstrate novel dynamics of the protein CBX binding to chromatin. CBX recruits the polycomb repressive complex 1 (PRC1) and is very important in establishing heterochromatin domains. Numerous previous studies relied on immunofluorescence to detect CBX proteins; however, such a strategy is unable to detect whether the protein is actually interacting with chromatin. Of course, ChIP can detect specific chromatin interactions, but those studies lack spatial information. Using BiFC to CBX and histones, the patterns of chromatin interacting versus total CBX were quite distinct. Thus, BiFC allows measurement of spatial, contextual, and temporal changes in protein complexes and will likely be an important tool in detecting the dynamics of nuclear compartmentalization.

In summary, live cell imaging techniques are poised to take advantage of the many genome-wide molecular assays that are currently being employed to describe genome-wide nuclear associations to uncover the mechanisms and consequences of nuclear architecture and organization on gene activity. Using the well-established *lacO*/LacI system and other techniques such as BiFC and nascent RNA detection methods in living cells will enable spatial, temporal, and molecular analysis to be carried out in a single cell giving an unprecedented view of the form and function of nuclear dynamics.

Glossary

Deuterium ractionation factor The equilibrium constant for exchange of a proton with the deuterons in D_2O .

Isotope shift The upfield perturbation of a nuclear magnetic resonance signal of an atom when a heavy isotope is substituted for it.

Transition state analog A stable molecule that has nearly all of the structural features of a transition state.

Proteins contain mainly weak, conventional hydrogen bonds; however, a few enzymes have low-barrier hydrogen bonds (LBHBs) in transition state analog complexes. Hydrogen bonds display variations in physicochemical properties including length, spectroscopic characteristics, and strength. Three classes of hydrogen bonds have been defined – weak ($2\text{--}8\text{ kcal mol}^{-1}$), strong ($10\text{--}20\text{ kcal mol}^{-1}$), and very strong ($24\text{--}40\text{ kcal mol}^{-1}$). In a weak hydrogen bond, the proton is bonded to one heteroatom by a dipolar covalent bond and engages in a weak electrostatic attraction with another heteroatom. In a strong hydrogen bond, or LBHB, the heteroatoms are closer than a van der Waals contact, the covalent bond to the proton is elongated, and the contact between the proton and the second heteroatom is significantly shorter than in a weak hydrogen bond. In a very strong, or single-well hydrogen bond, the heteroatoms are much closer than a van der Waals contact, and the proton is nearly centered between them. LBHBs in proteins and small molecules are characterized by their spectroscopic and thermodynamic properties, deuterium fractionation factors, and crystallographic structures. LBHBs have been identified in transition state analog complexes of a few enzymes and are postulated to stabilize the transition states in catalysis.

The Nature of Hydrogen Bonds

Hydrogen bonds were controversial throughout the twentieth century. By mid-twentieth century, the weak conventional hydrogen bonds were reasonably well understood and widely accepted. Unlike covalent bonds, which vary in strength within a factor of ~ 4 ($30\text{--}120\text{ kcal mol}^{-1}$), hydrogen bonds are much less constrained in their geometry and physical properties, and they vary in strength by a factor of at least 20-fold ($2\text{--}40\text{ kcal mol}^{-1}$). Very few strong hydrogen bonds had been documented before the mid-twentieth century, principally the very strong hydrogen bond in hydrogen difluoride $[F\cdots H\cdots F]^-$ (40 kcal mol^{-1}). Such strong hydrogen bonds were thought to be limited to crystalline states. In the latter half of the century, strong hydrogen bonds were discovered in several classes of organic molecules in crystals and aprotic liquid phases and characterized by crystallographic, spectroscopic, and chemical methods.

Weak, Strong, and Very Strong Hydrogen Bonds

The distinctions among hydrogen bonds can be illustrated by the differences among their energy profiles, as shown in Figure 1. Figure 1(a) is the energy profile for a weak hydrogen bond, that in Figure 1(b) is for a strong or LBHB, and that in Figure 1(c) is for a single-well or very strong hydrogen bond. The three classes are sometimes referred to as weak, moderate, and strong hydrogen bonds. Most hydrogen bonds in proteins and nucleic acids involve oxygen or nitrogen as the heteroatoms. For that reason, the hydrogen bonding properties delineated below refer to N or O as heteroatoms. Larger or smaller heteroatoms such as sulfur or fluorine display analogous properties with physical parameters outside the ranges for N and O.

Weak Hydrogen Bonds

As illustrated in Figure 1(a), the hydrogen (or deuterium) is confined to covalent bonding with one heteroatom by the fact that their zero-point vibrational energies are much lower than the barrier separating the heteroatoms. The covalent bond linking the electronegative atom to a hydrogen is dipolar, with a partial positive charge on the proton and a partial negative charge on the heteroatom. The electrostatic attraction between the proton and another partially negative heteroatom is a weak hydrogen bond. The strengths of weak hydrogen bonds range between 2 and 8 kcal mol^{-1} , depending on the type of heteroatoms, their electrostatic charge, the distance separating them, and the dielectric medium. Because they are weak, conventional hydrogen bonds easily undergo exchange with protons of water, with enthalpies of activation on the order of $2\text{--}3\text{ kcal mol}^{-1}$.

LBHBs – Strong Hydrogen Bonds

In an LBHB (Figure 1(b)) the heteroatoms are closer together and separated by significantly less than the van der Waals contact distance. As a consequence, the energy barrier between them is lowered to the range of the zero point vibrational energy for hydrogen, so that the hydrogen feels increased attraction to the other heteroatom and is drawn away from the first heteroatom, $A\cdots H$ in Figure 1(b). Deuterium feels less

Figure 1 In (a), the double well potential for a proton covalently bonded to heteroatom A and weakly hydrogen-bonded to heteroatom B is illustrated. The zero point energies for H and D are both well below the barrier, and both are strictly covalently bonded to A. In (b) for an LBHB, the heteroatoms are drawn close together in violation of van der Waals contact distance, the proton is moved toward B and away from A, and the barrier is lowered to near the zero point energy of H. The zero point energy of D is lower, so that deuterium is less attracted to B. In (c) for a single-well hydrogen bond, the heteroatoms are even closer together, and the proton is nearly centered between them. In the LBHB and SWHB, the bonding of the proton to heteroatom B is partially covalent.

attraction to the second heteroatom, owing to its lower zero point energy. Because of this difference, an LBHB displays deuterium and tritium isotope effects. LBHBs are stronger ($10\text{--}20\text{ kcal mol}^{-1}$) than weak hydrogen bonds because of the partial covalency between hydrogen and the second heteroatom, $\text{H}\cdots\text{B}$ in **Figure 1(a)**. As they are strong, LBHBs undergo exchange with protons of water less readily than weak hydrogen bonds. In an LBHB, the proton is strongly held, and the activation enthalpy for exchange with the protons of water is much higher than the $\sim 3\text{ kcal mol}^{-1}$ for a weakly hydrogen bonded proton. For LBHBs in proteins, the activation enthalpies for exchange are typically $10\text{--}19\text{ kcal mol}^{-1}$.

Single-Well or Very Strong Hydrogen Bonds

In a single-well hydrogen bond the heteroatoms are so close together that the zero point energies of both hydrogen and deuterium lie above the barrier, as in $\text{A}\cdots\text{H}\cdots\text{B}$ of **Figure 1(c)**. The proton is almost equally bonded between the heteroatoms and is nearly centered between them. Perfectly symmetrical, single-well hydrogen bonds are the strongest, $24\text{--}40\text{ kcal mol}^{-1}$, and are observed in very few small molecules. Such hydrogen bonds have not been detected in proteins.

Physicochemical Properties

Bond Lengths

Weak hydrogen bonds

The covalent bond length ($\text{O}, \text{N}\text{--}\text{H}$) is about $0.95\text{ \AA}$, the length of the electrostatic contact with the second heteroatom is $\geq 1.7\text{ \AA}$, and the separation between the heteroatoms is $\geq 2.6\text{ \AA}$ for $\text{O}\cdots\text{O}$, $\geq 2.7\text{ \AA}$ for $\text{O}\cdots\text{N}$, and $\geq 2.8\text{ \AA}$ for $\text{N}\cdots\text{N}$. Distances separating the heteroatoms can vary from the minima quoted above to as much as $3.5\text{ \AA}$.

LBHBs

In an LBHB (**Figure 1(b)**) the covalent bond is elongated to $1.05\text{--}1.1\text{ \AA}$, and the distance to the second heteroatom is

shortened, for example, to $1.4\text{--}1.5\text{ \AA}$. The separation between heteroatoms is shortened to $\leq 2.6\text{ \AA}$ for $\text{O}\cdots\text{O}$, $\leq 2.7\text{ \AA}$ for $\text{O}\cdots\text{N}$, and $\leq 2.8\text{ \AA}$ for $\text{N}\cdots\text{N}$. A short contact distance between heteroatoms is necessary but not sufficient for an LBHB. To be an LBHB, the hydrogen must be positioned in alignment with the heteroatoms. If the hydrogen is out of alignment, the hydrogen bond will be weak. In the strongest LBHBs, the proton affinities of the heteroatoms are similar or identical. The pK_a of the conjugate acid of a heteroatom is a measure of proton affinity, and heteroatoms in functional groups with similar or identical values of pK_a form the strongest hydrogen bonds.

Single-well hydrogen bonds

The hydrogen lies nearly equidistant from the heteroatoms and is approximately equally shared. The hydrogen is $1.2\text{--}1.3\text{ \AA}$ from each heteroatom, depending on whether it is O or N. Perfectly symmetrical hydrogen bonds are rare and so far observed only in small molecules incorporating special structural constraints that favor single-well hydrogen bonding. Single-well hydrogen bonds range in strength from 24 to 40 kcal mol^{-1} and are the strongest hydrogen bonds. They are formed between heteroatoms of functional groups with identical values of pK_a , in molecules or lattices in which the groups are held in close proximity.

Spectroscopic Properties

Weak hydrogen bonds

The nuclear magnetic resonance (NMR) chemical shift of the proton ranges between 9 and 11 ppm and does not display an isotope effect (isotope shift) upon replacement with deuterium or tritium.

LBHBs

Due to the elongated bond to the hydrogen, $\text{A}\cdots\text{H}$ in **Figure 1(b)**, the proton is substantially deshielded from the nonbonding electrons of the heteroatom. Consequently, the NMR signal for an LBHB involving O or N is downfield in the range of $18\text{--}20\text{ ppm}$ on the chemical shift scale. In the

absence of an internal magnetic effect, such as complexation with a paramagnetic metal ion, a downfield chemical shift is a strong indicator of an LBHB or single-well hydrogen bond. In an LBHB as in **Figure 1(b)**, the zero point energy difference between hydrogen and deuterium leads to deuterium and tritium isotope effects on the NMR signal, with that for deuterium falling upfield by up to 0.6 ppm from that for hydrogen.

As the proton in an LBHB interacts with both heteroatoms to a greater degree than a deuterium, there is an isotope effect on the infrared stretching frequency. The ratio of stretching frequencies $\nu_{\text{OH}}/\nu_{\text{OD}}$ for O–H and O–D engaged in an LBHB differs from the ratio typical of weak hydrogen bonds. For weak hydrogen bonds $\nu_{\text{OH}}/\nu_{\text{OD}} = 1.4$ and represents the mass difference between hydrogen and deuterium. For an LBHB, $1.0 \leq \nu_{\text{OH}}/\nu_{\text{OD}} < 1.4$ in small molecules. This is because of the greater strength of the LBHB with H than with D, and the difference in strength arises because of the differential interactions of H and D with the barrier in **Figure 1(b)**. This property of LBHBs in small molecules has been extensively documented. Among the physicochemical properties that have been used in characterizing LBHBs, the deuterium isotope effect on the infrared stretching frequencies is the only one that has not been applied to LBHBs in proteins.

Single-well hydrogen bonds

Single-well hydrogen bonds display downfield NMR signals at 21–22 ppm when the heteroatoms are O or N. Because the zero point energies of both H and D lie above the barrier in **Figure 1(c)**, single-well hydrogen bonds do not display deuterium or tritium isotope effects on NMR signals. They also do not display deuterium isotope effects on infrared stretching frequencies, that is, $\nu_{\text{OH}}/\nu_{\text{OD}} = 1.4$.

Deuterium Fractionation Factors

Weak hydrogen bonds

Weakly hydrogen bonded protons display deuterium fractionation factors Ψ of about 1.0–1.2. The fractionation factor is the equilibrium constant for the exchange of hydrogen-bonded protons with deuterons in deuterium oxide. A fractionation factor of 1.0 means that deuterons and protons are bound with equal affinities.

LBHBs

In an LBHB, hydrogen is more strongly bonded than deuterium because of the effect illustrated in **Figure 1(b)**. Therefore, the deuterium fractionation factor Ψ for an LBHB is less than 1.0, typically 0.3–0.7.

Single-well hydrogen bonds

In a single-well hydrogen bond, the zero point energies of both H and D lie above the barrier, so that they interact similarly with both heteroatoms. Therefore, the fractionation factor is generally ~ 1.0 .

LBHBs in Enzymes

Serine Proteases

An LBHB was first assigned to the proton bridging His57 and Asp102 in chymotrypsin at low pH and in transition state

analog complexes of chymotrypsin. The assignment was based initially on the downfield NMR chemical shift for this proton of 18.0 ppm for chymotrypsin at low pH and 18.9 ppm for chymotrypsin a transition state-analog complex, and on the close contact between His57 and Asp102 ($< 2.6 \text{ \AA}$) in crystal structures of transition state analog complexes. The LBHB was postulated to stabilize the transition state and facilitate its formation. It was shown in this connection to increase the basicity of His57. The characterization of this LBHB in several transition state analog complexes was completed by measurements of its fractionation factor of 0.3–0.4, its enthalpy of activation for exchange of 14–19 kcal mol^{−1}, and the deuterium and tritium isotope effects on its NMR chemical shifts. The role of the LBHB in catalyzing the formation of the acyl-chymotrypsin intermediate in the action of chymotrypsin is illustrated in **Figure 2**. In resting chymotrypsin, His57 is not protonated and is engaged in weak hydrogen bonding with Asp102. His57 abstracts the proton from Ser195 as it attacks the acyl carbonyl group of a substrate to form the tetrahedral

Figure 2 The role of the LBHB in the mechanism of acylation of serine proteases. In the Michaelis complex, the active site histidine (His57 in chymotrypsin numbering) is neutral and weakly hydrogen bonded to Asp201. In the first step, His57 abstracts a proton from Ser195 as it undergoes nucleophilic addition to the substrate carbonyl group. As His57-Nε2 becomes protonated, the hydrogen bond between His57-Nδ1 and Asp-Oδ2 becomes a strong LBHB, and this increases the basicity of His57 as it enters the transition state. The LBHB stabilizes the transition state and transient tetrahedral intermediate. In the second step, His57-Nε2 donates the proton to the N-terminal amino group of the leaving peptide.

intermediate. In the transition state for proton abstraction, His57 becomes protonated on His57-N ϵ 2, and the LBHB is formed between His57-N δ 1 and Asp102. The resulting LBHB stabilizes the transition state and tetrahedral adduct and thereby facilitates the formation of the metastable intermediate. The LBHB maintains the basicity of His57 with a pK_a of 10.6 to 12, intermediate between that of Ser195 (13.4) and that of the amino terminus (9.2) of the peptide leaving group. Thus, the LBHB makes His57 an optimal acid/base catalyst for the acylation of Ser195 by a peptide substrate.

Evidence, similar to but less extensive than that above, for chymotrypsin has been obtained for other serine proteases, especially trypsin and subtilisin. The crystal structure of subtilisin at 0.78 Å resolution shows electron density for hydrogen in the LBHB linking His64 and Asp32. The electron density for the proton places it 1.2 Å from His57-N δ 1 and 1.5 Å from Asp32-O δ 2. ¹⁵N NMR analysis of the LBHB in a transition state analog complex of subtilisin indicates that the proton, 20–30%, is transferred toward Asp32. Both the crystallography and NMR spectroscopy verify that this is an LBHB and support its catalytic role as originally postulated in the action of chymotrypsin.

Serine Esterases

Serine esterases have catalytic triads similar to serine proteases and function by a similar mechanism. Extensive NMR analysis of the hydrogen bond, linking the active site histidine with the active site glutamate, documents the presence of an LBHB.

Δ^5 -3-Ketosteroid Isomerase

The isomerization requires the enolization of the 3-keto group of the substrate to form a homoenolate anion as a metastable intermediate. The homoenolate is within hydrogen bonding distance of Tyr14, and the pK_a of the homoenol is similar to that of tyrosine or phenol. The phenolic inhibitor dihydroequilinen forms an LBHB with Tyr14 in analogy with a putative LBHB in the complex of the metastable homoenolate with Tyr14. The LBHB displays the properties including a downfield NMR signal, low deuterium fractionation factor, and close contact in the crystal structure. The LBHB is postulated to stabilize the homoenolate and thereby facilitate its formation in the catalytic mechanism.

This article is reproduced from the previous edition, volume 2, pp. 599–601, © 2004, Elsevier Inc.

Glossary

Erythema Redness of the skin due to capillary dilatation or proliferation.

Hypermetabolism A condition of enhanced metabolic activity in one or more tissues, resulting in increased heat production by the body, typically associated with hyperthyroidism.

Polydipsia Prolonged excessive thirst and excessive intake of liquids.

Polyphagia Excessive eating.

Tachycardia Rapid beating of the heart, usually above 90 beats min^{-1} .

Luft's disease is an extremely rare human disorder characterized by loose coupling of mitochondrial oxidative phosphorylation in skeletal muscle, that is, loss of the control normally exerted by adenosine triphosphate on the rate of respiration of muscle mitochondria. Although described only in two patients, Luft's disease is of great historical importance because it was the first example of organellar medicine and it opened the field of mitochondrial diseases, which has expanded into a large and complex area involving all subspecialties of medicine.

Clinical Considerations

Both patients were women, one from Sweden and the other from Jordan, without any family history of similar disorders. The clinical hallmark was hypermetabolism, with fever, heat intolerance, profuse perspiration, polyphagia, polydipsia, and tachycardia at rest. Although both patients suffered from exercise intolerance, weakness was mild. The Jordanian patient also had diffuse erythema of the legs due to capillary proliferation, maybe an attempt by the body to create a radiator to facilitate heat dispersion. The initial diagnosis was hyperthyroidism, but Rolf Luft, an endocrinologist at the Karolinska Institute in Stockholm, ruled out this possibility and astutely suggested that mitochondrial dysfunction of skeletal muscle, the most abundant tissue in the body, could underlie this condition. A muscle biopsy confirmed that mitochondria were excessively numerous and morphologically abnormal, and polarographic studies of isolated mitochondria showed loose coupling. The paper describing these findings is a classic of clinical investigation, which amply justifies the eponym.

Onset of symptoms had been in childhood in both patients, and the course was slowly but relentlessly progressive: both women died, in their middle ages, of respiratory failure. Autopsies were not performed, but clinical evidence strongly suggests that the disease is confined to skeletal muscle, as heart function was normal and there were no symptoms of central nervous system involvement. Electromyography was compatible with myopathy.

Therapy

In 1971, Haydar employed a naive but pioneer approach to gene therapy in the second patient with Luft's disease, who was given chloramphenicol to inhibit mitochondrial protein synthesis and reduce her basal metabolic rate. During the first trial, some reduction of the basal metabolic rate was achieved and was accompanied by mild subjective improvement, but the second trial had to be interrupted because of drug toxicity.

Muscle Biopsy

Morphology

In both women, there was massive proliferation of mitochondria, documented with the modified Gomori trichrome histochemical stain by the presence of ragged-red fibers in the second patient, and by electron microscopy in both patients. Ultrastructurally, there were large pools of mitochondria, predominantly under the sarcolemma. Many of the mitochondria were greatly enlarged and contained tightly packed cristae, some also contained abnormal osmiophilic inclusions (Figure 1). Intramuscular capillaries were overabundant.

Figure 1 Morphology of a muscle biopsy from the second patient with Luft's disease. The left panel shows the histochemical stain of a frozen section with the modified Gomori trichrome, which reveals abnormal accumulations of mitochondria as reddish blotches (ragged-red fibers). The right panel is an electron micrograph showing a portion of one fiber (bottom) with normal morphology. The adjacent fiber (top) shows massive accumulation of mitochondria under the cell membrane. The accumulated mitochondria are greatly enlarged and have tightly packed cristae.

(a)

(b)

Figure 2 Polarographic tracings of isolated muscle mitochondria from the second patient with Luft's disease (b) and from a normal individual (a). Note how addition of micromolar amounts of adenosine diphosphate (ADP) stimulate oxygen uptake in normal mitochondria, but not in the patient's mitochondria, whose rate of respiration is maximal after the addition of substrates (pyruvate + malate). This high rate of respiration is neither stimulated by ADP nor inhibited by oligomycin. This condition, in which adenosine triphosphate is formed normally but does not control the rate of respiration, is defined 'loose coupling' of oxidation and phosphorylation.

A skin biopsy in the second patient was normal, except for capillary proliferation.

Biochemistry

In polarographic studies of isolated skeletal muscle, mitochondria showed maximal oxygen consumption (respiratory rate) even in the absence of adenosine diphosphate, indicating that respiratory control was lost, although phosphorylation capacity was normal (Figure 2). Spectra and content of cytochromes were normal, and the activities of individual enzymes of the respiratory chain were also normal. However, basal adenosine triphosphatase activity was greatly increased and poorly stimulated by the uncoupler 2,4-dinitrophenol.

In 1976, DiMauro et al. found in the second patient that the rate of energy-dependent calcium uptake by isolated mitochondria was normal, but the amount of calcium accumulated decreased, and intramitochondrial calcium could not be retained and was quickly released into the medium. A vicious cycling of calcium uptake and release was proposed as a mechanism to explain the waste of electrochemical energy as heat.

Genetics

The lack of maternal inheritance, the apparent muscle specificity of the disease, and the lack of large-scale rearrangements of mitochondrial DNA in the second patient are circumstantial evidence that Luft's disease may be due to a nuclear DNA defect. Thus, the molecular basis of the prototypical mitochondrial myopathy remains obscure 40 years after Luft described the first patient, a situation made more difficult by the fact that only one other patient with Luft's disease has been identified; both patients are deceased, and no tissues are available, except fibroblasts from the second patient.

Major Sperm Protein and Sperm Locomotion

K Shimabukuro and T M Roberts, Florida State University, Tallahassee, FL, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Actin Cytoskeletal protein found in nearly all eukaryotic cells. Self-assembly of actin monomers form filaments that impart organizational and mechanical properties in cells and participate in activities ranging from whole cell migration to cytokinesis.

Cell body The trailing portion of a crawling cell, usually packed with organelles, including the nucleus and mitochondria.

Cytoskeleton A network of protein polymers involved in cell structure, organization, and motility.

Lamellipod The flattened forward region of a crawling cell containing the cytoskeletal components responsible for powering motility.

Major sperm protein (MSP) It forms the filaments that comprise the cytoskeleton of nematode sperm, also functions as a signaling molecule.

Protrusion The forward extension of the leading margin of a crawling cell.

Retraction The process that pulls the cell body of a crawling cell forward behind the motile lamellipod.

Nematode Sperm Motility

Nematode sperm lack a flagellum, and, instead, locate eggs by amoeboid locomotion (Figure 1(a)). The movement of nematode sperm is practically indistinguishable from that of other amoeboid cells but they have discarded the actin-based motility apparatus that normally powers crawling movement. These cells have replaced actin with a dynamic cytoskeleton constructed from major sperm protein (MSP). Like actin, MSP polymerizes to form filaments that pack the lamellipod responsible for pulling the cell over its substratum. The organization and dynamics of the MSP cytoskeleton are displayed in a particularly prominent fashion in sperm from the large parasitic nematode, *Ascaris suum*, where the MSP filaments are arranged into several long, branched meshworks, called 'fiber complexes' that span the length of the lamellipod (Figure 1(b)). The fiber complexes are assembled at the leading margin of the lamellipod and taken apart at its base and, thus, treadmill rearward as the sperm moves forward. The rates of cytoskeletal assembly and disassembly are balanced and coupled to the rate of sperm locomotion. Disruption of this finely tuned cytoskeletal choreography, for example, via an uncoupling of fiber complex assembly from its disassembly, has shown that both processes are required for sperm movement. Assembly of MSP produces a force required for protrusion of the leading edge of the lamellipod while disassembly

is involved in creating a retraction force that pulls the cell body forward.

MSP as a Signaling Molecule

MSP had been known as a cytoskeleton protein for several years when Greenstein and colleagues made the surprising discovery that MSP leads a double life as an extracellular signaling molecule. In *Caenorhabditis elegans*, MSP derived from sperm is a bipartite signaling factor that stimulates both oocyte meiotic maturation and contraction of a smooth-muscle-like gonadal sheath cell that surrounds the proximal oocyte, resulting in the release of an egg from the ovary to the spermatheca, the sperm-storage compartment where fertilization takes place. The N-terminal portion of MSP promotes oocyte maturation while the C-terminal part of the molecule stimulates sheath cell contraction. Several aspects of this part of the double life of MSP remain to be unraveled. For example, in order to carry out this signaling function, MSP must be secreted from the lamellipod into the extracellular space. However, sperm are cells ultimately specialized for motility that discard the standard components for secretion very early in their development. Further, MSP lacks an N-terminal signal sequence. Thus, secretion of the protein occurs through unconventional mechanism that appears to involve the budding of small MSP-packed

Figure 1 (a) A scanning electron micrograph of a crawling *C. elegans* sperm. These cells crawl by extending a motile lamellipod to grip the substratum and pull the hemispherical cell body forward. (b) Two images of a crawling *Ascaris* sperm illustrating the dynamics of fiber complexes within lamellipod. The time interval between the two images is 10 s. The MSP fiber complexes are readily visible by light microscopy, so their dynamics can be followed without using invasive methods. The fiber complexes treadmill through the lamellipod by assembling at the front and disassembling at the rear. The arrowhead indicates a branch in a fiber complex that remains stationary relative to the substratum as the cell progresses. Scale = 2 μm in (a) and 5 μm in (b). (b) From Italiano JE, Stewart M, and Roberts TM (1999) Localized depolymerization of the major sperm protein cytoskeleton correlates with the forward movement of the cell body in the amoeboid movement of nematode sperm. *Journal of Cell Biology* 146: 1087–1095.

vesicles from the sperm lamellipod. The released vesicles then break down allowing MSP to spread into the oviduct.

Molecular Biology and Biochemistry of MSP

MSP, which was first reported in sperm from *C. elegans*, is a 14-kDa protein found exclusively in nematode sperm. As implied by its name, MSP is the most abundant protein in sperm and comprises about 40% of soluble protein in the cell. Although MSP forms the cytoskeleton within the lamellipod of sperm, it does not have any sequence homology to other cytoskeletal proteins such as actin, tubulin, or intermediate filament proteins.

All nematode species that have been examined, including free-living and parasitic forms, have MSP genes. The sequences are well conserved and exhibit at least 80% amino acid identity between species. The numbers of copies of MSP genes differ considerably among species. For example, *C. elegans* has as many as 50 MSP genes and pseudogenes whereas *Ascaris suum* contains only two genes.

MSP from *A. suum* has been studied more extensively than that from other species because the abundance of sperm from these large parasites made it relatively easy to obtain large quantities of the protein. There are two isoforms of MSP in *Ascaris*, named α and β , each composed of 126 amino acids and differing at only four residues. Both isoforms contain an acetylated N-terminal alanine, but no other posttranslational modifications have been detected. β -MSP is slightly less basic (pI 8.3 vs. 8.9) and fivefold more abundant than α -MSP. Both isoforms form homodimers in solution. Monomers are tightly associated ($K_d < 50$ nM) in the dimer, implying that almost all of the unpolymerized MSP in sperm, where the free MSP concentration is ~ 2 mM, is dimeric.

Figure 2 The structure of MSP and the filaments it forms. (a) A ribbon diagram showing the structure of a dimer of α -MSP from *Ascaris* based on X-ray crystallographic analysis. MSP contains a seven-stranded β sandwich with opposing three-stranded and four-stranded β sheets. (b) MSP filaments assembled in a cell-free extract of *Ascaris* sperm and prepared as a platinum replica. Scale = 0.5 μm . (a) From Roberts TM and Stewart M (2000) Acting like actin. The dynamics of the nematode major sperm protein (MSP) cytoskeleton indicate a push-pull mechanism for amoeboid cell motility. *Journal of Cell Biology* 149: 7–12.

Structure of MSP

Structural analysis of *Ascaris* α -MSP by X-ray crystallography and NMR spectroscopy showed that the MSP polypeptide chain has an immunoglobulin-like fold based on a seven-stranded β sandwich with opposing three-stranded and four-stranded β sheets (Figure 2(a)), a feature shared with the N-terminal domain of PapD, a bacterial chaperone involved in assembly of the flagellar rod. However, PapD and MSP do not appear to share a common function. The MSP dimer is a symmetric molecule in which the two subunits are related by twofold rotational symmetry, a property that has important consequences for the structure and function of MSP filaments.

Purified MSP polymerizes into filaments when incubated in a solution containing 30% ethanol. Although this is not physiological, the filaments formed in ethanol are indistinguishable from native filaments obtained from lysed sperm. Each filament is 11 nm in diameter and composed of two helical subfilaments that are wrapped around one another. The polymerizing unit is the symmetric dimer, and the way that these subunits are arranged to form subfilaments produces an MSP

Figure 3 *In vitro* reconstitution of MSP-based motility. (a) Time lapse sequence showing the elongation of a fiber *in vitro*. Addition of ATP to cell-free sperm extract triggers MSP assembly on the surface of spherical vesicle derived from the leading edge membrane of lysed sperm. Polymerizing MSP forms a cylindrical meshwork of filaments, called a ‘fiber’, behind the vesicle. Growing fibers push their vesicle forward in the same manner as the fiber complexes in crawling sperm push the leading edge membrane forward (see [Figure 1\(b\)](#)). (b) An image of a platinum replica of a fiber showing the spherical vesicle at the head of a column of tightly packed MSP filaments. (c) Time lapse sequence of images illustrating retraction of a fiber that has been treated with sperm extract supplemented with PTPase. Note the pronounced shrinkage of the fiber over time accompanied by the decrease in its optical density indicative of the gradual disassembly of the constituent filaments. Scale = 5 μm in (a) and (c), 1 μm in (b).

filament with no structural polarity. This property sets MSP filaments apart from actin filaments and microtubules where structural polarity is critical to important such processes as polymerization kinetics, operation of motor proteins, intracellular organization, and interaction with accessory proteins.

In Vitro Reconstitution of the MSP Motility Apparatus

The MSP motility apparatus from *Ascaris* sperm has been reconstituted *in vitro* by the addition of adenosine triphosphate (ATP) to cell-free sperm extracts. Under these conditions, MSP filaments assemble at the surface of small vesicles, derived from the lamellipodial plasma membrane, which contain the MSP nucleation machinery. This site-directed polymerization produces dense meshworks of filaments behind the vesicle, called ‘fibers’ ([Figures 3\(a\)](#) and [3\(b\)](#)). As the fibers grow they push their vesicles forward in the same way that MSP polymerization into fiber complexes pushes the plasma membrane at the leading edge of the lamellipod forward in crawling sperm.

The *in vitro* motility system has also been used to reconstitute the cytoskeletal dynamics underlying the retraction of the cell body that occurs in crawling sperm. Treatment of fibers with cell-free sperm extract supplemented with a protein tyrosine phosphatase (PTPase) caused the filaments within the fiber to disassemble and, surprisingly, also led to a dramatic shrinkage of the fiber along its length ([Figure 3\(c\)](#)) generating sufficient force to move plastic beads attached to the shortening fiber. By contrast, fibers treated with buffer alone disassemble slowly without appreciable shrinkage. Subsequent assays showed that the PTPase that induces fiber retraction works by activating a serine/threonine phosphatase in the sperm extract. This activity was eventually traced to a protein phosphatase 2A (PP2A) present in the sperm extract. The disassembly associated shrinkage of fibers in response to phosphatase treatment is similar to the disassembly mediated shortening of the fiber complexes at the base of the sperm lamellipod that generates the retraction force that pulls the cell body forward.

Table 1 Known MSP cytoskeletal proteins

Protein	Isoforms	Localization	Function
MSP	α, β	Lamellipod, cytosolic	Subunit of filaments
MFP1	α, β, γ	Lamellipod, cytosolic	Fiber-binding protein, inhibits fiber growth, capping protein?
MFP2	a, b, c	Lamellipod, cytosolic	Fiber-binding protein, accelerates polymerization, threonine-phosphorylated protein
MFP3		Lamellipod, cytosolic	Fiber-binding protein, stabilizes filaments? Threonine-phosphorylated protein
MPOP		Leading edge membrane	Membrane-embedded protein forms nucleation complex with MPAK, tyrosine-phosphorylated protein
MPAK		Leading edge membrane	Ser/Thr kinase, forms nucleation complex, phosphorylates MFP2
PP2A		Lamellipod–cell body interface	Phosphatase, triggers retraction Dephosphorylates MFP3

MSP Accessory Proteins

The versatility of the reconstituted MSP motility system suggests that it contains all of the components needed for both protrusion and retraction. Therefore, fibers became a valuable starting point for the isolation and identification of the accessory proteins involved in sperm locomotion. Stepwise dissection of fibers led, thus far, to the discovery of six such proteins ([Table 1](#) and [Figure 4](#)).

MSP-Organizing Protein

MSP-organizing protein (MPOP) is a 48-kDa integral membrane phosphotyrosine protein and the only membrane

Figure 4 Model of the biochemical basis of the MSP assembly-disassembly cycle associated with motility in sperm. In the schematic drawing of the whole sperm, the MSP filaments that make up a fiber complex are shown in red. At the leading edge of sperm (right inset), tyrosine-phosphorylated MPOP recruits MPAK to the membrane and forms a nucleation complex. MPAK, then, activates MFP2 by phosphorylation which, in turn, stimulates MSP assembly by an unknown mechanism. MSP polymerization may be terminated by MFP1. Phosphorylated MFP3 binds to and may, in fact, stabilize, the newly polymerized filaments. The filaments then treadmill to the base of the lamellipod where they disassemble (left inset). PP2A concentrated at the cell body-lamellipod junction is activated by a PTPase and dephosphorylates MFP3, causing release of MFP3 and depolymerization of the filaments.

protein required for MSP polymerization. Phosphorylated MPOP localizes to the leading edge of crawling sperm where MSP assembles into filaments and forms fiber complexes and is also found in the membrane of the vesicles that assemble fibers *in vitro*. The phosphorylation of MPOP is pH sensitive and its dephosphorylation at low pH results in the loss of polymerization-inducing activity. Only a partial amino acid sequence of MPOP is available and there is, as yet, no significant homology to known proteins from other types of organisms.

MSP Polymerization-Activating Kinase

MSP polymerization-activating kinase (MPAK) is a 34-kDa putative Ser/Thr kinase that exhibits sequence homology to several members of the casein kinase 1 family. MPAK is a cytosolic component but is recruited to the membrane surface by binding to phosphorylated MPOP. Thus, MPAK is located at sites of cytoskeletal assembly *in vivo* and *in vitro* where it phosphorylates a protein required for MSP polymerization at the membrane (see below).

MSP Fiber Protein 2

MSP fiber protein 2 (MFP2) is a cytosolic component in the MSP cytoskeleton that is required for fiber assembly *in vitro*. There are three MFP2 isoforms: a, b, and c, that range in molecular weight from 38 to 41 kDa. MFP2 is phosphorylated on a threonine residue by MPAK, and the phosphorylated form

of the protein incorporate into the fiber. The rate of fiber elongation *in vitro* is directly related to the concentration of MFP2 in the sperm extract but the exact role of MFP2 in MSP polymerization is not known. Crystal structures of both MFP2a and MFP2b revealed that both isoforms consist of two similar domains connected by a linker.

MSP Fiber Protein 1

MSP fiber protein 1 (MFP1) is also a cytosolic component that is incorporated into the MSP cytoskeleton as it is assembled. Although it binds to fibers, MFP1 is not essential for MSP polymerization and also has no known role in retraction. MFP1 causes a concentration-dependent decrease in the rate of fiber growth *in vitro*. There are three MFP1 isomers: α , β , and γ , all of which are acidic proteins ($pI=4.5$) with molecular weights of about 16 kDa. MFP1 contains an MSP domain, which has led to speculation that it may function as a capping protein by binding to the ends of filaments thereby blocking or hindering the addition of MSP dimers to the polymer.

MSP Fiber Protein 3

MSP fiber protein 3 (MFP3) is a 43-kDa cytosolic threonine-phosphorylated protein that contains 19 tandem repeats of a 15-residue motif in the middle of its sequence. Each repeat has at least one threonine residue that can be phosphorylated. The phosphorylated form of the protein binds to MSP filaments but the number of phosphorylated residues required for binding has

not been defined. Upon dephosphorylation, MFP3 is released from the filament and the loss of MFP3 leads to the depolymerization associated with fiber retraction. Therefore, multiple phosphorylation of MFP3 could, in principle, generate a molecule with a large negative charge that could bind to and stabilize filaments constructed from positively charged MSP dimers.

Protein Phosphatase 2A

The discovery that protein phosphatases trigger retraction of fibers led to the identification of an endogenous PP2A in *Ascaris* sperm. This phosphatase is concentrated at the cell body–lamellipod junction where fiber complexes are taken apart. Purified PP2A from sperm can induce retraction *in vitro* in absence of any other soluble components in cell-free extract. Moreover, the activity of this PP2A itself is regulated by phosphorylation. Thus, the induction of retraction by the sperm PP2A is activated by tyrosine dephosphorylation, a property consistent with the observation that sperm extract supplemented with PTPase triggers fiber shrinkage.

Mammalian DNA Methyltransferase Structural Themes

X Cheng and H Hashimoto, Emory University School of Medicine, Atlanta, GA, USA

© 2013 Elsevier Inc. All rights reserved.

Introduction

In mammals and other vertebrates, DNA methylation occurs at the C5 position of cytosine (5mC), mostly within CpG dinucleotides (Figure 1(a)), with the Dnmt enzymes using a conserved mechanism that has been studied best in the bacterial 5mC methyltransferase M.HhaI. Briefly, this mechanism involves methyltransferase binding to the DNA, eversion of the target nucleotide so that it projects out of the double helix (base flipping), covalent attack of a conserved Cys nucleophile on cytosine C6, transfer of the methyl group from S-adenosyl-L-methionine (AdoMet) to the activated cytosine C5, and the various release steps. This methylation, together with histone modifications, plays an important role in modulating chromatin structure, thus controlling gene expression and many other chromatin-dependent processes. The resulting epigenetic effects maintain the various patterns of gene expression in different cell types. In mammals, Dnmts include three members, in two families, that are structurally and functionally distinct (see below). The Dnmt3a and Dnmt3b establish the initial CpG methylation pattern *de novo*, while Dnmt1 maintains this pattern during chromosome replication and repair (Figure 1(b)).

Dnmt3 Family

The Dnmt3 family includes two active *de novo* Dnmts, Dnmt3a and Dnmt3b, and one regulatory factor, Dnmt3-like protein (Dnmt3L) (Figure 2(a)). Dnmt3a and Dnmt3b have similar domain arrangements: both contain a variable region at the N-terminus, followed by a PWWP (Pro-Trp-Trp-Pro) domain that may be involved in nonspecific DNA binding or binding of histone H3 trimethylated at lysine 36, a Cys-rich 3-Zn binding ADD (ATRX-DNMT3-DNMT3L) domain, and a C-terminal catalytic domain. The amino acid sequence of Dnmt3L is very similar to that of Dnmt3a and Dnmt3b in the ADD domain, but it lacks the conserved residues required for DNA methyltransferase (MTase) activity in the C-terminal domain.

Dnmt3L is a Regulatory Factor for *De Novo* DNA Methylation

The phenotype of Dnmt3L knockout mice is indistinguishable from that of a Dnmt3a germ cell-specific conditional knockout, with both having altered sex-specific *de novo* methylation of DNA sequences in germ cells and dispersed retrotransposons. These results indicate that Dnmt3a and Dnmt3L are both required for the methylation of most imprinted loci in germ cells. The minimal regions required for interaction between Dnmt3L and Dnmt3a, and for stimulated activity, are in the C-terminal domains of both proteins. The overall Dnmt3a/Dnmt3L

C-terminal complex is ~16 nm long, which is greater than the diameter of a 11-nm core nucleosome (Figure 2(b)). This complex contains two monomers of Dnmt3a and two of Dnmt3L, forming a tetramer with two 3L–3a interfaces and one 3a–3a interface (3L–3a–3a–3L). Substituting key noncatalytic residues at the Dnmt3a–3L or Dnmt3a–3a interfaces eliminates enzymatic activity, indicating that both interfaces are essential for catalysis.

Dimeric Dnmt3a Suggests *De Novo* DNA Methylation Depends on CpG Spacing

Among known active DNA MTases, Dnmt3a and Dnmt3b have the smallest DNA-binding domain (though it is absent altogether in Dnmt3L). However, dimerization via the 3a–3a interface yielded a model such that the two active sites are located in the DNA major groove and dimeric Dnmt3a could methylate two CpGs separated by one helical turn in one binding event (Figure 2(c)). A periodicity in the activity of Dnmt3a on long DNA substrates revealed a correlation of methylated CpG sites at distances of ~10 base pairs, and the structural model of oligomeric Dnmt3a docked to DNA may explain this pattern. Similar periodicity is observed for the frequency of CpG sites in the differentially methylated regions of 12 maternally imprinted mouse genes. These results suggest a basis for the recognition and methylation of differentially methylated regions in imprinted genes, involving detection of both CpG spacing and histone modification (see the next section). CpG DNA methylation patterns in human chromosome 21 are correlated with the CpG periodicity of ~10 base pairs. An ~10 base-pair periodicity has also been evident for non-CpG methylation in embryonic stem cells. Non-CG methylation disappeared upon induced differentiation of the embryonic stem cells and was restored in induced pluripotent stem cells. Similarly, a 10-bp correlation of non-CpG DNA methylation by *Arabidopsis thaliana* DRM2 (which is related to mammalian Dnmt3a) has been observed.

Dnmt3L Connects Unmethylated Histone H3 Lysine 4 to *De Novo* DNA Methylation

Genome-scale DNA methylation profiles suggest that DNA methylation is better correlated with histone methylation patterns. Specifically, DNA methylation is correlated with the absence of histone H3 lysine 4 (H3K4) methylation and the presence of histone H3 lysine 9 (H3K9) methylation. Considering the inverse relationship between H3K4 methylation and DNA methylation, it is important to note that mammalian LSD1 and LSD2, two related lysine-specific demethylases whose substrates include di- and mono-methylated H3K4 (H3K4me2/me1), are absolutely essential in maintaining

Figure 1 DNA cytosine methylation, hydroxylation, and demethylation. (a) The question mark indicates possible activity of DNA demethylases. Tet indicates conversion of 5mC to 5hmC in mammalian DNA, by the MLL fusion partner TET1. The double question mark indicates that it is currently unknown whether 5hmC is an end product or an intermediate in active DNA demethylation. (b) Maintenance versus *de novo* methylation. The pale-blue rectangular segments are substrate sequences (usually CpG), and the turquoise shapes represent methyl groups on the cytosines. After replication or repair, the duplex is methylated on one strand only (hemi-methylated).

Figure 2 Dnmt3a. (a) Schematic representation of Dnmt3 family. (b) A model of interactions between Dnmt3a-3L tetramer and a nucleosome. A nucleosome is shown, docked to a Dnmt3L-3a-3a-3L tetramer (3a-C in green; 3L full length in gray). The position of a peptide derived from the sequence of the histone H3 amino terminus (purple) is shown, taken from a cocrystal structure with this peptide bound to Dnmt3L. By wrapping the tetramer around nucleosome, the two Dnmt3L molecules could bind both histone tails from one nucleosome. (c) The Dnmt3a dimer could, in theory, methylate two CpGs separated by one helical turn in one binding event. (d) Structure of Dnmt3L with a bound histone H3 N-terminal tail (orange).

global DNA methylation or establishing maternal DNA genomic imprints, respectively. Indeed, disruption of LSD1 results in earlier embryonic lethality and a more severe hypomethylation defect than disruption of the Dnmt's themselves.

The mammalian *de novo* DNA methylation Dnmt3L-Dnmt3a machinery could translate patterns of H3K4 methylation into

heritable patterns of DNA methylation that mediate transcriptional silencing of the affected sequences. Dnmt3a and Dnmt3b bind nucleosomal DNA. Dnmt3a2 is a shorter isoform of Dnmt3a that is also required for genomic imprinting. Dnmt3a2 and Dnmt3b, along with the four core histones, were identified as the main *in vivo* interaction partners of

epitope-tagged Dnmt3L. Peptide interaction assays showed that Dnmt3L specifically interacts with the extreme amino terminus of histone H3; this interaction was strongly inhibited by H3K4 methylation, but was insensitive to modifications at other positions. Co-crystallization of Dnmt3L with the amino tail of H3 showed this tail bound to the ADD domain of Dnmt3L (Figure 2(d)), and substitution of key residues in the binding site eliminated the H3–Dnmt3L interaction. These data suggest that Dnmt3L is a probe of H3K4 methylation, and if the methylation is absent then Dnmt3L induces *de novo* DNA methylation by docking activated Dnmt3a to the nucleosome.

Histone–Dnmt3L–Dnmt3a–DNA interactions have been studied in the budding yeast *Saccharomyces cerevisiae*, which has no detectible DNA methylation and lack Dnmt orthologs. Introduction of the murine methyltransferase Dnmt1 or Dnmt3a in yeast leads to detectible but extremely low levels of DNA methylation. By contrast, a substantially higher level of *de novo* methylation could be achieved in yeast by coexpressing murine Dnmt3a and Dnmt3L. This induced DNA methylation was found preferentially in heterochromatic regions where H3K4 methylation is rare. When genes for components of the H3K4-methylating complex COMPASS/Set1 were disrupted in the context of Dnmt3a/3L overexpression, a greater level of genomic DNA methylation was observed. Deletions or targeted mutations in the ADD domain of Dnmt3L inhibited both global DNA methylation and the ability of Dnmt3L to associate with an H3K4me0 peptide (Figure 2(d)). These same Dnmt3L mutants failed to restore normal DNA methylation to a specific promoter when introduced into embryonic stem cells from Dnmt3L^{−/−} mice.

Structure of Dnmt1

The large Dnmt1 protein contains multiple functional domains (1619 residues for mouse Dnmt1 and 1616 residues for human DNMT1) (Figure 3(a)): an N-terminal region that interacts with Dnmt1 associated protein(s) (DMAP1), followed by a methylation and phosphorylation switch between an adjacent lysine and serine that determines Dnmt1 stability, a proliferating cell nuclear antigen (PCNA) interacting sequence, a replication foci targeting sequence (RFTS) that interacts with the SET- and RING-associated (SRA) domain of UHRF1, a CpG-interacting CXXC domain, a tandem bromo-adjacent homology (BAH) domain, and a DNA methyltransferase domain including the target-recognizing domain (TRD) at the C-terminus.

Two structures are currently available for mouse Dnmt1: a large fragment (residues 357–1612) of Dnmt1 in complex with AdoMet or its product S-adenosyl-L-homocystein (AdoHcy) and a shorter fragment (residues 651–1600) bound to DNA-containing unmethylated CpG sites. In the absence of DNA, the N-terminal RFTS domain is inserted into the DNA-binding surface cleft (Figure 3(b)), indicating that this domain must be removed for methylation to occur. When the isolated RFTS domain added in trans to the RFTS-lacking Dnmt1 protein, the RFTS domain is a DNA-competitive inhibitor of Dnmt1. In the structure of the shorter Dnmt1 fragment, in the absence of the linked RFTS domain, the DNA-bound CXXC domain positions itself in the catalytic domain and prevents aberrant *de novo* methylation of CpG sequence (Figure 3(c)). Thus, a multistep process accompanied by structural changes must occur during maintenance methylation

Figure 3 Dnmt1. (a) Schematic representation of Dnmt1. (b) Structure of mouse Dnmt1 (residues 357–1612) containing RFTS (green), CXXC (red), BAH1 (front), and BAH2 (back) in dark blue, and C-terminal MTase domain with TRD in orange (PDB 3AV4). (c) Structure of mouse Dnmt1 (residues 651–1600) with the CXXC domain specifically bound to DNA containing an unmethylated CpG site (PDB 3PT6).

of hemi-methylated CpG DNA by removing both RFTS and CXXC domains away from the catalytic center.

The SRA Domain of UHRF1 Flips 5-Methylcytosine Out of the DNA Helix

An accessory protein UHRF1 (ubiquitin-like, containing PHD and RING finger domains 1) (**Figure 4(a)**) targets Dnmt1 to hemimethylated replication forks (and presumably repair sites). The crystal structure of the SET and RING associated (SRA) domain of UHRF1 in complex with DNA containing a hemimethylated CpG site was determined. They reveal that the SRA domain flips the 5-methylcytosine (5mC) completely out of the DNA helix (**Figure 4(b)**) and is positioned in a binding pocket. The structure also suggests an explanation for the preference for hemimethylated sites. In the major groove side, a backbone carbonyl oxygen is close to the C5 ring carbon of the unmethylated cytosine, forming a $C=O \cdots H-C$ hydrogen bond. The addition of a methyl group to C5 of the unmethylated cytosine would cause a steric clash between the methyl group and SRA.

DNA methyltransferases or DNA repair enzymes use base flipping to gain access to a DNA base to perform chemistry on it, but the SRA domain probably uses base flipping to increase its protein–DNA interface and to prevent the SRA domain from linear diffusion away from the site on the DNA. This may be particularly important for the SRA domain, as its recognition sequence is only two base pairs. We suggest

that the SRA–DNA interaction (through recognition and flipping of the 5mC) serves as an anchor to keep UHRF1 at hemimethylated CpG site where it recruits Dnmt1 for maintenance methylation, and perhaps other proteins such as DNA repair enzymes for mismatch repair. The 5mC base flipping by the SRA domain might also provide a more general mechanism to distinguish the methylated parental strand from the unmethylated daughter strand, an ability particularly important for mismatch repair if an error occurs during DNA replication. Supporting this hypothesis, the expression of UHRF1 is deregulated in cancer cells, and mouse UHRF1-null cells are more sensitive to DNA-damaging agents and DNA replication arrest.

DNA Demethylation via Hydroxylation?

5-Hydroxymethylcytosine (5hmC) has long been noted in bacterial phage, and its presence in mammalian cells was believed to be a by-product of oxidative DNA damage. Recently, using isolated relatively homogenous populations of Purkinje and granule neuronal nuclei of adult mouse brains, Kriaucionis and Heintz found that significant fractions (~40%) of cytosine nucleotides correspond to 5hmCs, the amount of which inversely correlates with 5mC and nuclear heterochromatin in neurons (Kriaucionis and Heintz, 2009). Even more fascinating, a conserved mammalian-specific family of ten-eleven translocation (TET) proteins that converts 5mC to 5hmC (**Figure 1(a)**) was identified. Overproduction of TET1 in human cells led to the appearance of 5hmC. A concomitant reduction in DNA 5mC indicated that 5hmC is an oxidation product of 5mC. 5hmC was detected in embryonic stem cells, especially enriched at the start sites of genes whose promoters bear ‘bivalent’ marks – dual H3K27me3 and H3K4me3 marks. The surprising finding of a 5mC oxidation pathway raises numerous questions, such as whether oxidation of 5mC is an important epigenetic modification, either as an end product or as an intermediate in active DNA demethylation, as supported by the presence of 5hmC DNA excision repair glycosylase. New lines of research will likely be catalyzed by the presence of 5hmC in mammalian DNA.

DNA Demethylation via Glycosylation?

A recent study reported that MBD4, a protein containing an N-terminal methyl-CpG-binding domain (MBD) and a C-terminal glycosylase domain, is phosphorylated via protein kinase C (PKC) by parathyroid hormone stimulation (**Figure (5)**). Phosphorylated MBD4 promotes incision of methylated DNA through glycosylase activity, and a base-excision repair process seems to complete DNA demethylation in the MBD4-bound promoter. Such parathyroid-hormone-induced MBD4 phosphorylation and subsequent DNA demethylation and transcriptional derepression are impaired in Mbd4^{-/-} mice.

Summary

The experimental characterizations of Dnmts and their associated protein factors provide a rapid and convergent picture

Figure 4 UHRF1. (a) Schematic representation of UHRF1 – a multi-domain protein. (b) Structure of SRA–DNA complex. The 5mC flips out and is bound in a cage-like pocket involving hydrogen bonding and van der Waals interactions (inserted).

of the kinetic mechanisms (autoinhibition of Dnmt1 by RFTS domain), binding partners such as UHRF1-Dnmt1 and Dnmt3L-Dnmt3a, chromatin recognition such as binding of H3K4me0 by Dnmt3L, RNA-directed DNA methylation, methylation–phosphorylation-dependent regulation of Dnmt1 stability, phosphorylation-induced MBD4 activity, and the discovery of 5hmC in mammalian genome. However, understanding the basis for establishing, maintaining, and disturbing DNA methylation patterns will require a much better understanding of the union between structure and function in the Dnmts and their associated protein factors than we currently possess. Without understanding the interactions and spatial relationships between their modular domains, or whether inter-domain interactions contribute to target specificity, it is not possible to construct a temporal sequence of events or causal relationships in gene silencing.

Glossary

Collisional cross-section The cross-section of a molecular structure that can undergo collisions with a buffer gas, averaged over all orientations.

Electrospray ionization Method of producing gas phase molecular ions by the application of voltage to a solution; solvent evaporation and charge-induced fission result in multiply charged protein ions.

Ion mobility spectrometry Measurement of mobility of ions through a buffer gas under the influence of an electric

field; mobility of an ion is determined by its mass, charge, and physical size.

Native mass spectrometry Mass analysis of molecular structures, whereby the analyte retains as much as possible its ternary and quaternary solution phase structure.

Tandem mass spectrometry The mass analysis of molecular structures prior to and subsequent to a gas phase reaction, typically an activation/dissociation event.

Introduction

The association of proteins into large and functional assemblies is essential for life; indeed, the average number of interacting partners of a protein during its lifetime is thought to be as high as eight. The resulting complexes can be large and heterogeneous, as well as dynamic, which can make the study of their structural properties challenging. Mass spectrometry (MS) offers a unique possibility to analyze intact protein complexes in a native-like state, over a theoretically unlimited mass range. This allows the deduction of information regarding the structure and dynamics of these assemblies. Native MS is a comparatively new and increasingly popular technology for such applications, and provides important information highly complementary to other techniques commonly used in structural biology and molecular biophysics.

Structural Biology Analysis of Protein Complexes

There is increasing demand for structural biological studies of large protein complexes and assemblies, and a concomitant requirement for applicable techniques. Native MS is a unique method, allowing determination of and insight into overall mass of a protein complex, stoichiometry, mass of composite subunits, subunit arrangement, complex stability, and dynamics. Furthermore, recent coupling of ion-mobility spectrometry (IMS) with native MS has added a new dimension to these analyses, whereby the overall size or shape of the analyte can additionally be measured. Thus, the data obtained from native MS can bridge the gap between high-resolution nuclear magnetic resonance (NMR) and X-ray crystallography structures, usually limited to relatively small macromolecules, and high-throughput protein identification and interactomics studies.

Native MS Methodology and Instrumentation

In order to analyze proteins and protein complexes by MS, they must first be transferred from solution phase to gas phase, while maintaining native contacts and native (or native-like) structure. The most effective ionization technique for achieving this is nano-electrospray ionization (nanoESI), a miniaturized version of ESI, a method widely exploited for the MS analysis of biomolecules. Importantly, for nanoESI, protein complexes can be in aqueous solutions at neutral pH, in which they will generally populate native states. Due to the vaporization step necessary prior to MS, the presence of involatile salts and buffers is problematic; a typical buffer-like salt adopted for native MS analyses, to circumvent this problem, is ammonium acetate. During nanoESI, solvent and buffer evaporate, leaving multiply charged macromolecular ions (**Figure 1**). With this soft ionization technique, native structure can to a certain degree be retained; for protein complexes, this means the retention of both tertiary and quaternary structure.

The production of protein ions with multiple charges by ESI results in numerous peaks on a mass-to-charge (m/z) scale, with each peak relating to a different charge state of the same protein (**Figure 1**). The molecular mass of the protein (or complex) can be determined from these charge-state peaks. Furthermore, the charge state of a protein, that is, the number of protons which have associated during the ESI process, is related to the conformational state of the protein. Compact, folded conformations obtain fewer charges than extended, unfolded conformations, due to the decreased number of solvent-accessible basic sites, and thus the two different states will result in discrete charge-state distributions within a mass spectrum.

In order to analyze the protein complex ions produced by ESI, a mass spectrometer with a large m/z range accessible is typically necessary. For these purposes, time-of-flight (ToF) or hybrid ToF (e.g., quadrupole time-of-flight, Q-ToF) mass

Figure 1 (Left) Schematic of nanoESI, whereby multiply charged protein ions are produced after a voltage is applied to a capillary. (Right) Typical mass spectrum of a multiply charged protein ionized by ESI. Different types of MS experiments, and the information gained from them, are listed (CID=collision-induced dissociation, HDX=hydrogen-deuterium exchange, IMS=ion-mobility spectrometry).

analyzers are usually employed. ToF instruments have theoretically unlimited m/z ranges, although some instrumental challenges currently impose a maximum on the achievable values. Modifications have been made to Q-ToF instruments to improve the transmission and detection efficiency of large macromolecular ions, and ions can now be observed up to approximately m/z 100 000. An important adaptation is to increase the pressure in certain regions within the mass spectrometer, which results in improved transmission of large noncovalent ions. Other modifications include the use of low-frequency quadrupoles, as well as low-frequency ToF pusher voltages, to allow ions with high m/z values to traverse these sections of the mass spectrometer.

In addition to the mass spectral information typically obtained from these instruments, performing MS in combination with other experimental techniques (summarized in [Figure 1](#)), such as hydrogen-exchange, cross-linking, and IMS, can provide many data regarding biophysical properties of macromolecules. Tandem MS (MS/MS) experiments are commonly used to glean more information regarding the structural properties of the complex. In Q-ToF instruments, a collision cell between the quadrupole and ToF analyzers is filled with an inert gas, such as argon, and acceleration of the ions through this cell causes energetic collisions. This activation can result in dissociation of a protein complex into composite parts (collision-induced dissociation, CID), which are then identified by the ToF MS.

Recent instrumental developments have allowed the integration of IMS into MS experiments on large protein complexes. This technique can be seen as a gas phase equivalent of gel filtration chromatography, and adds another dimension of analysis or separation, based on the mobility of ions

traveling through a gas-filled cell. This provides a measurement of the ion's collisional cross-section, an indication of the overall size and shape of the ion. The ability to gain such additional information is enhancing further the application of native MS within the structural biology field.

Protein Complex Composition

The measurement of molecular weight of a native protein complex can provide direct evidence for or confirmation of the subunit stoichiometry. By denaturing the complex, for example, using organic or acidic solution modifiers (a mixture of acetonitrile or methanol with formic acid or trifluoroacetic acid is often utilized in MS), the masses of the individual composite subunits can be measured, to aid in interpretation of the mass of the intact complex.

An example of the use of native MS in confirming the stoichiometry of a large, homo-oligomeric complex is in the study of the hepatitis-B virus (HBV) capsid. This particle was previously known to populate two different morphologies, with the number of subunits assumed from their symmetry. The two particles were confirmed by MS experiments to contain 180 or 240 copies of the subunit monomer, as determined from the measured masses of 3.012 and 4.014 MDa ([Figure 2](#)). MS has also been used to determine for the first time the composition of the yeast RNA polymerase III. It was shown that this complex contained a single copy of each of the 17 subunits previously identified. Furthermore, the capability of MS to observe simultaneously populated species also revealed the presence of a complex lacking a heterodimer of two of the subunits. The tryptophan RNA-binding

Figure 2 NanoESI mass spectrum of hepatitis-B virus capsids. Two distinct charge-state distributions are observed, corresponding to two stoichiometries of subunit assembly: 180 subunits (measured mass 3012 kDa, pink) and 240 subunits (measured mass 4014 kDa, blue). Inset: capsid particles as visualized by cryo-electron microscopy, showing two distinct geometries (indicated by arrowheads). Scale = 50 nm.

attenuation protein (TRAP) was known to populate a homo-oligomeric 11-mer state, and had been proposed also to form higher order structures. MS was used to analyze TRAP in the presence of trp ligand to identify both the oligomeric composition of the complex, and its binding behavior. In addition to the 11-mer, a 12-mer TRAP complex was identified, which was found to bind 11 trp ligands, and also a TRAP24-trp22 complex. These findings not only confirmed the composition of TRAP complexes, but additionally gave insights into how the oligomers assemble, and differences in trp binding.

Dynamic Protein Complexes

MS analyses of protein complexes can be performed on a relatively fast timescale (data can be acquired within a few minutes). This, plus the advantage of monitoring copopulated species, allows dynamic processes to be followed in real time. Reactions between different protein complexes can be studied, with the relative rates of reactant decrease and product formation being measured, as well as the possibility to observe and identify on-pathway intermediates. This can reveal important information about kinetic processes and reaction mechanisms. For example, the ordered assembly of specific subunits into bacterial pilus fibers was shown to be kinetically controlled using time-resolved MS studies. Monitoring the transthyretin tetramer as a function of time by MS also revealed very interesting behavior regarding the exchange of subunits in and out of this oligomer, which is involved in systemic amyloid disease. Using stable isotope labeling to increase the molecular weight of a fraction of the proteins, the rate of exchange could be measured. Mixing the wild-type with a variant which is particularly associated with amyloidosis, L55P, showed the formation of mixed tetramers. Interestingly, it was also found that the L55P affected the rate of wild-type transthyretin dissociation. In this way, information about the formation of hybrid tetramers, with important biological implications, was obtained from native MS experiments.

A great advantage of MS is that it can be utilized to analyze systems of a very complex and dynamic nature. An example of this is in the analysis of an intricate circadian clock system from cyanobacteria, which can be reproduced *in vitro* with three proteins. Native MS has been used to identify the many different complexes these proteins form, as well as monitoring their appearance and disappearance throughout this cyclic reaction.

Topology of Complexes and Assembly Pathways Determined by Dissociation

The use of CID can provide information about the quaternary structure and overall architecture of protein complexes. This process is analogous to CID of peptides or small molecules, where the activation energy eventually causes fragmentation of covalent bonds, but here, the activated complex generally loses a single, noncovalently bound subunit. The dissociating subunit is typically highly charged compared to the remaining subcomplex; indeed, it is thought that the dissociation occurs concomitantly with subunit unfolding, explaining the ability of this protein to sequester a high proportion of the protons. Which subunit dissociates first from a complex is apparently dependent on two factors: first, how strong or extensive interactions are with other subunits; second, whether the subunit is located at the periphery or in the core of the complex. This is well demonstrated by CID experiments on the wild-type and a variant of the 20S proteasome complex from *Rhodococcus*. The K151A/K153A variant forms a $\alpha_7\beta_7$ structure, where a ring of α subunits is bound face-to-face with a ring of β subunits. When subjected to collisional activation, a β subunit is released (**Figure 3(a)**); this is likely due to the lower area of surface contact between β subunits (800 Å²) compared to between α subunits (1440 Å²). However, in the wild-type complex, a $\alpha_7\beta_7\beta_7\alpha_7$ structure is formed, whereby two β rings are sandwiched between two α rings. In this case, collision activation induces the loss of an α subunit, since the topology of the complex prevents the

Figure 3 Tandem MS (CID) spectra of (a) K151A/K153A and (b) wild-type 20S proteasome, showing dissociation of beta (green) or alpha (blue) subunits. Inset (a) shows contact surface area of alpha and beta subunits.

dissociation of a β monomer (Figure 3(b)). Thus, it is clear that CID MS can provide information regarding the overall topology of protein complexes.

An alternative angle from which to approach the deduction of the topology of a protein complex is to use partial denaturation in solution to produce subcomplexes of the overall assembly. In this way, local protein interactions can be mapped, and the location of different subunits in relation to each other determined. Indeed, using different dissociation methods allows a wide range of different subcomplexes to be identified, and thus extensive maps of the topology of complexes to be determined. For example, in combination with computational modeling, MS data has provided a detailed picture of the quaternary structure of the yeast RNA exosome, a complex containing 10 distinct subunits. Thus, the use of either gas-phase (CID) or solution-phase dissociation evidently allows important structural information of large, homo- or heterogeneous protein complexes to be obtained.

Maintaining Native Structure/Function in the Gas Phase

An important question to address when using MS in the analysis of protein complexes is to what extent the native structure is maintained during the course of the experiment. Whether or not the structures of gas phase complexes bear close resemblance to those they adopt in solution has been the subject of

wide debate. Obviously, the desolvation of such a molecule is likely to significantly affect the native interactions it forms, altering the viability and/or strength of hydrophobic and electrostatic interactions, and hydrogen bonds. However, many factors can affect whether structural features are maintained or not, including the identity of the complex of interest, the retention of residual interfacial or surface-bound solvent molecules, and the number of charges obtained during the ESI process. Much evidence is being accrued for the validity of gas phase analyses in determining solution phase properties. For example, the tobacco mosaic virus capsid was subjected to ESI-MS, after which it was collected and analyzed by transmission electron microscopy, revealing that it retained its native three-dimensional structure. Moreover, it was proven still to be infective, implying that the particle either remains unchanged throughout the MS process, or undergoes only changes that are reversible upon rehydration.

The recent advent of IMS hyphenated with MS for the analysis of large proteins and complexes has allowed more proof of the retention of native structures to be gathered. In a seminal IMS-MS study of protein complexes, the native ring structure of the oligomeric TRAP complex was seen to be preserved in the gas phase. A measurement of the size of an ion, the collisional cross-section, can be extracted from IMS data, and compared to structural models of a molecule, for example, from X-ray crystallography or computational methods. In the case of TRAP, and many other proteins and complexes, reasonable agreement is seen between the IMS-MS data and the solved structures.

Figure 4 (a) Mass spectrum and associated ion mobility drift time data for GroEL alone and bound to a substrate, gp23. (b) Collisional cross-sections for complexes of unbound GroEL, GroEL–GroES, GroEL–gp23, and GroEL–GroES–gp23.

However, the effect of charge can be apparent on gas phase structures, in that a high number of charges can give rise to an extended or even a collapsed protein structure. Thus, although native or native-like structures evidently can be studied by ESI–MS, it is always wise to interpret such data with care.

IMS–MS is increasingly being applied as an analytical tool to study biological systems. One such study focused on the GroEL–GroES chaperonin system. Substrate polypeptides were seen to remain bound to the chaperonin in the gas phase (Figure 4(a)). Furthermore, the dimensions of the GroEL or GroEL–GroES complexes were found not to change upon substrate binding, implying that the substrate is trapped inside the hollow structure (Figure 4(b)). These results are part of the cumulating evidence that protein assemblies can largely retain their solution phase structural properties in the gas phase.

Pushing the Boundaries of Native MS

Native MS is increasingly being used for the study of native complexes and their structural and biophysical properties. Complexes can now be analyzed into the megaDalton range, and thus with particle sizes of tens of nanometers. Although the theoretical size of particles measurable by MS is unlimited, practicalities currently prevent the analysis of much larger complexes. Some problems also arise with charge-state resolution and complete desolvation, as well as assignment of charge states for accurate mass assignment. Continuing instrument and software development should aid with the improvement of such factors. Furthermore, parallel improvements in the resolution and calibration of IMS, as well as the continuing advance in computational modeling methods, should further the level of detail possible from IMS–MS experiments.

One field of structural biology very challenging for MS is the analysis of membrane proteins and complexes thereof. Recent developments, however, have pushed this field forward. It has been shown that ESI of a micelle containing a protein complex, followed by CID of the detergent molecules

within the micelle, allow intact complexes of membrane proteins to be analyzed by MS. This opens up an avenue for extending the application of native MS to samples not previously possible.

Another area in which native MS of protein complexes is likely to be increasingly exploited is in biopharmaceutical research. Here, it can be applied to numerous analytical problems, including protein ligand screening, measuring antibody–antigen interactions, epitope mapping, and monitoring conformational changes. The ability to obtain unique information, with a fast data acquisition time and low sample consumption, means that this technique fits ideally into the niche of biopharmaceutical analysis. As native MS pushes the boundaries of the analysis of protein complexes, its application range broadens, and it is proving to be an invaluable tool in many areas of structural biology.

Glossary

Chiasma The point where homologous chromosomes exchange arms. Chiasmata (pl.) are the cytological manifestations of crossing-over.

Crossing-over A reciprocal exchange between two DNA molecules. This occurs via the DNA-repair process called homologous recombination.

Homologous recombination A DNA repair process in which a broken chromosome uses a homologous DNA sequence (generally located on a different chromosome) as a template for its repair.

Ploidy The number of copies of the genome or the number of chromosome sets in a cell. Haploid, one genome and

one set of chromosomes; diploid, two copies of the genome and two sets of chromosomes; and aneuploid cells have unbalanced sets of chromosomes, that is, at least one extra or one missing chromosome.

Sister-chromatid cohesion The connections that hold newly replicated chromosome pairs together until they are ready to be distributed into daughter cells.

Synaptonemal complexes Proteinaceous structures, resembling zippers or railroad tracks, which assemble between homologous chromosomes during meiosis. Synaptonemal complexes hold chromosomes together during the pachytene stage and promote the formation of chiasmata.

Meiosis is the specialized type of cell division by which gametes are produced. This process achieves the remarkable feat of halving the chromosome complement of a cell, typically from diploid to haploid. Meiosis thereby allows the diploid state to be restored when two gametes fuse during fertilization to form a zygote. Reduction of ploidy during meiosis occurs because two successive rounds of chromosome segregation follow a single round of DNA replication. The first round of chromosome segregation is unique in that the sister chromatids remain associated while parental homologs (pairs of sisters) are segregated. As prerequisites for their accurate segregation, homologs become closely paired along their lengths, by a structure called the synaptonemal complex (SC), and then undergo crossing-over – a reciprocal exchange of chromosome arms between two nonsister chromatids. Homolog pairing and crossing-over both involve homologous recombination, which occurs by the programmed formation and repair of DNA double-strand breaks (DSBs). Crossing-over is an essential feature of meiosis that underlies the fundamental laws of heredity: first, crossovers are essential for genetic transmission because they create connections between homologs that facilitate their bipolar orientation on the segregation apparatus (the spindle) and thereby facilitate orderly segregation. Second, crossovers (together with the independent assortment of parental chromosomes) produce diverse combinations of alleles on which genetic selection can act. Defects in meiotic chromosome segregation are linked to infertility, miscarriage, and genetic disease in humans.

The Sexual Life Cycle

In sexually reproducing organisms, successive generations maintain a constant number of chromosomes. This is because syngamy, the fusion of two gametes to form a zygote

(that subsequently gives rise to a new individual), is alternated with meiosis, which halves the cellular chromosome number. Without meiosis, syngamy would result in an unsustainable doubling of the chromosome content with each successive generation. Thus, the alternation of diploid (two copies of each chromosome) and haploid (one copy of each chromosome) generations of cells is a fundamental feature of most sexually reproducing organisms. In metazoans, syngamy is typically followed by extensive cell proliferation, by mitosis, and the development of a new individual. Meiosis in metazoans occurs exclusively in the germ-line cells of the gonads.

Mitotic and Meiotic Chromosome Cycles

Understanding how meiosis achieves the remarkable feat of halving the cellular chromosome number first requires an appreciation of how cells segregate chromosomes during mitotic cell division ([Figure 1](#)).

Mitosis

During mitosis, copies of both maternal and paternal chromosomes are distributed to two daughter cells. Replication first produces two identical copies of each chromosome called sister chromatids ([Figure 1](#), top row, panel ii.). Microtubules of the spindle apparatus attach to the chromatids via complex protein structures called kinetochores, which assemble at a unique location on each chromosome called a centromere ([Figure 1](#), top row, panel iii.). The chromatid pairs are then pulled apart to opposite poles of the cell, which then divides ([Figure 1](#), top row, panel iv.). The result is two identical daughter cells each containing two complete (maternal and paternal) sets of chromosomes. Two interdependent features ensure that chromosome segregation is an accurate process:

Figure 1 Comparison of Mitotic and Meiotic chromosome cycles (see text for details). Arrows indicate directions of the pulling forces generated by microtubules. Dashed lines indicate the planes of cell division.

(1) connections between sister chromatids and (2) a checkpoint mechanism that senses when each pair of chromatids has become attached to microtubules emanating from both poles of the spindle. Connections between sister chromatids, called sister-chromatid cohesion, form during replication and hold the sister chromatids together until they are ready to be segregated. When the two kinetochores of a sister-chromatid pair are attached to microtubules emanating from opposite poles of the cell, the pulling forces of the spindle are resisted by the cohesion between sister centromeres. The resulting tension stabilizes the microtubule-kinetochore attachments. When all chromatid pairs have achieved this biorientation on the spindle, sister-chromatid cohesion is destroyed and chromatids are pulled to the cell poles.

Meiosis

Meiosis, like mitosis, begins with replication to produce pairs of sister chromatids connected by cohesion (Figure 1, bottom row, i and ii). Then, in contrast to mitosis, a single copy of every chromosome must be accurately distributed to four different nuclei. Meiosis achieves this in the only logical way: via two successive rounds of nuclear division, first segregating homologs (the maternal and paternal chromatid pairs) and then segregating sister chromatids, as in mitosis. Regular homolog segregation is unique to meiosis, but utilizes the same mechanical principles as mitotic chromosome segregation. Thus, four modifications to the mitotic chromosome cycle are required:

1. Maternal and paternal homologs associate and become connected by structures known as chiasmata (Figure 1, bottom row, panel iii. and Figure 2). A chiasma results from crossing-over: the reciprocal breakage and joining of a maternal with a paternal chromatid. A chiasma holds the homologs together by virtue of the sister-chromatid

cohesion that was established as the chromosomes were replicated. Chiasma formation is the physical basis of genetic crossing-over.

2. The kinetochores of sister chromatids are modified such that they are unable to attach to microtubules emanating from different poles. Thus, the two sister kinetochores of a homolog behave like the kinetochore of a single sister chromatid in mitosis. Together with chiasmata, this monopolar property allows the homolog pair to biorient on the spindle. In this case, spindle forces are resisted by the combination of the connections between homologs and sisters (chiasmata and sister-chromatid cohesion; Figure 1, bottom row, panel iii.). The monopolar modification of sister kinetochores is reversed in preparation for the second meiotic division in order for sister chromatids to be segregated (Figure 1, bottom row, panel v).
3. The cohesion between the chromosome arms is destroyed prior to the first division, whereas cohesion between sister centromeres is protected until the second round of segregation ensues. This modification allows homologs to be segregated at the first meiotic division, while leaving sufficient cohesion to facilitate sister segregation at the second division (Figure 1, bottom row, panels iii–v).
4. The two meiotic divisions occur without an intervening round of replication by modulating the activities of cell-cycle kinases.

Meiotic Prophase I

The first meiotic division is preceded by a protracted G2 phase during which the chromosomes are paired and chiasmata are formed. This period is divided into five stages, defined by the appearance of the chromosomes under the light microscope (Figure 3):

Figure 2 Chiasmata in the migratory locust, *Locusta migratoria*. (Top row) Chiasmata are observed during three distinct stages of meiotic prophase I, after which the homologs are segregated. (Bottom row) Enlargements of individual homolog pairs; cartoons show the topological relationships between chromosomes and the points of exchange. Images kindly provided by Professor Gareth Jones, Birmingham University.

Images kindly provided by Professor Gareth Jones, Birmingham University. Reproduced from Funcham JRS (1983) *Genetics*. Sudbury, MA: Jones & Bartlett, with permission.

1. *Leptonema* (adjective = leptotene; from the Greek *lepto*, meaning 'thin'). During leptonema, which follows chromosome replication, chromosomes are first visible as long thin strands.
2. *Zygonema* (adjective = zygotene; from the Greek *zygo*, meaning 'yoke', Old English for couple or unite). Homologs begin to closely associate during zygonema. The extent of association increases throughout this stage.
3. *Pachynema* (adjective = pachytene from the Greek *pachy*, meaning 'thick'). Homologs are associated along their entire lengths and thus appear as thick, morphologically indistinguishable entities.
4. *Diplonema* (adj = diplotene; from the Greek *diplo*, meaning 'double'). Diplonema is usually preceded by the diffuse stage during which chromosomes appear fuzzy and indistinct. When they reappear at diplonema, homologs are no

longer associated along their lengths, but are visibly connected by chiasmata (Figure 2). In female animals, meiosis typically arrests after diplonema and oocytes move into a quiescent dictyate stage in which the chromosomes are less condensed. In most vertebrates, the first meiotic division is only completed in response to hormonal stimulation during ovulation.

5. *Diakinesis* (from the Greek *dia*, meaning 'across' and *kinesis*, meaning 'movement'). During diakinesis, the nuclear membrane begins to break down and spindle microtubules develop and connect to the monopolar kinetochores of the homologs. The homolog pairs condense dramatically, becoming progressively shorter and thicker and they move toward the equator of the cell (Figures 2 and 3).

After Prophase I

Following the events of prophase I, the cell prepares the chromosomes for segregation and then segregates them via two additional stages, which are the meiotic counterparts of the final stages of mitosis (Figure 3). A second round of chromosome segregation and differentiation of the gametes then ensues:

1. *Metaphase I* (from Greek *meta* = between, with, beside, after + *phasis* = appearance). At metaphase I, the condensed chromosomes are aligned along the equator of the spindle, typically at the central plane of the cell. This configuration is the consequence of stable biorientation of the homolog pairs on the spindle (Figures 2 and 3).
2. *Anaphase I* (from Greek *ana* = up, throughout, according to + *phasis* = appearance). At anaphase I, cohesion between chromosome arms is destroyed and the homologs are pulled toward the poles of the spindle.
3. *Telophase I and Interphase I* (from Greek *telos* = end; Latin *inter* = between, among; + Greek *phasis* = appearance). Telophase is the last phase of mitosis, in which the segregated chromosomes decondense and are enclosed in a new nuclear membrane. Interphase is any period or stage between two successive mitotic divisions. These stages are not a general feature of meiosis and in many cases are skipped as the cell proceeds directly to the second meiotic division. In metazoan oocytes, cell division is asymmetric, resulting in the production of a small polar body plus a large oocyte cell.
4. *Meiosis II*. During prophase II, the chromosomes recondense and spindle microtubules develop. The sister-chromatid pairs then attach to the spindle in a bipolar fashion and congress to the spindle equator at metaphase II. The oocytes of vertebrates arrest for a second time at metaphase II, where they remain until fertilization. Typically, the plane of the meiosis II spindles is perpendicular to that of the meiosis I spindle. Sister chromatids are pulled apart at anaphase II and new nuclear envelopes form during telophase II. In oocytes, a second polar body is formed and only one haploid gamete is produced from the four sets of chromosomes that were present in the original precursor cell.
5. *Gametogenesis*. At this stage, the products of meiosis are known as meiocytes. The differentiation of meiocytes then

produces gametes that are characteristic of the specific organism, for example, sperm, eggs, pollen, and spores.

Meiotic Chromosome Structure and the SC

Loops and Axes

Meiotic chromosomes have a well-defined loop-axis structure (Figures 4(a)–4(c)), which is revealed by ultrastructural studies using the electron microscope. The loops are loops of chromatin that vary in size from ~20 kb in simple protists like yeast to ~2500 kb in grasshopper, an organism with particularly large chromosomes. Thus, the large differences in genome size between different organisms are accommodated in large part by changes in chromatin loop size, such that meiotic chromosome length does not vary linearly with genome size. The loops of every pair of chromatids are connected at their bases, in a linear arrangement, along a rod-like axis or core, that is, one axis = two chromatids = one homolog. Protein constituents of the homolog axes include those involved in sister-chromatid cohesion. The basic loop/axis structure is thought to be organized by the cohesion proteins; this then serves as a platform for the binding of additional proteins whose binding gives rise to the distinct axes detected by electron microscopy (Figures 4(c)–4(f)).

Synaptonemal Complexes

Meiotic chromosome pairing culminates with the formation of SCs, prominent proteinaceous structures that form between homologs, along their entire lengths. SC morphology, as defined by ultrastructural studies, is remarkably conserved between different organisms (Figure 4(f)): two dense lateral elements flank a central region, which contains a less dense central element. The lateral elements correspond to the homolog axes, described above. Transverse filaments lie across the central region to create a striated, zipper-like appearance. Central region proteins (transverse filaments) share a broadly similar secondary structure; a long coiled-coil flanked by globular C- and N-termini. Coiled-coil lengths of ~70–90 nm fit the prediction that these proteins span the 100-nm central region in an overlapping head-to-head configuration. SCs are thought to assemble by a two-step process: nucleation, by installing central region proteins at sites where homolog axes are very closely paired, followed by polymerization between and along the homolog axes. SCs are important for the normal formation of chiasmata and may also help minimize chromosome entanglement and nonhomologous recombination.

Prophase I Stages at the Ultrastructural Level

The homolog axes develop and become distinct during leptotema. The homologs progressively pair, eventually becoming coaligned along their lengths at a distance of ≥ 400 nm. During this presynaptic alignment, axes closely associate at several sites along each pair of homologs. These axial associations are the sites where DNA molecules are interacting via homologous recombination and are often associated with densely staining nodular structures that contain recombination proteins (see below and Figures 4(d) and 4(e)). During zygonema,

the polymerization of SCs is nucleated at a subset of these sites. Cells enter pachynema when SCs extend along the lengths of every pair of homologs and a second type of nodular structure develops which is typically larger, denser, and rounder, and much less numerous than those observed during zygonema (Figure 4(f)). These late recombination nodules mark the sites where chiasmata will appear following the breakdown of SCs and entry into diplonema.

Homologous Recombination during Meiosis

Homologous recombination is a DNA repair process in which a broken chromosome uses a second homologous chromosome as a template for its repair. The central reaction of recombination involves the pairing and strand exchange between a DNA strand, from an end of a broken chromosome, and a

homologous template duplex. The resulting joint molecule (JM) intermediate, called a displacement loop (D-loop), provides a primer-template substrate for the new DNA synthesis required to repair the damaged chromosome. Each recombination event has one of two potential outcomes: a crossover (the reciprocal exchange of chromosome arms) or a noncrossover (a local transfer of genetic information without exchange of chromosome arms). Homologous recombination typically plays two successive roles during meiosis: (1) to mediate the close pairing of homologs during leptonema/zygonema and (2) to connect homologs via chiasmata from diplonema through to anaphase I.

Mechanism and Regulation of Meiotic Recombination

Meiotic recombination is initiated by the programmed formation of numerous DNA DSBs during leptonema (Figure 5).

Figure 5 Relative time line of the DNA events of recombination and the cytological stages of meiosis. (Top row) The stages of meiotic prophase I. In mammals, this period occupies about 3 weeks; in a simple protist like yeast, it takes just 5 h. (Middle row) Relative timing and molecular details of meiotic recombination. Each pair of lines represents a DNA duplex. All four chromatids are shown at the DSB stage, but for clarity only the two chromatids involved in the recombination event are shown in subsequent stages (see text for details). (Bottom row) Synaptonemal complex formation in baker's yeast, *Saccharomyces cerevisiae*. Spread meiotic chromosomes were stained with fluorescent antibodies to a synaptonemal complex protein.

In yeast and similarly in mouse and human, it can be inferred that ≥ 200 DSBs are formed per meiotic cell. Such a large number of recombination events are required to bring homologs into close register and facilitate the formation of SCs. Only a subset of DSBs ($\sim 5\text{--}30\%$ depending on the organism), go on to produce crossovers. The ends of DSBs are processed to give long single-stranded tails, which load proteins related to the bacterial recombinase, RecA. These RecA homologs have the amazing ability to coat a single strand of DNA and then rapidly locate and pair with an identical DNA sequence anywhere in the genome. Meiotic chromosomes use this homologous pairing activity to recognize and pair with their homologous partner during leptonema.

A key aspect of meiotic recombination is its regulation. To ensure that each pair of homologs becomes connected by chiasmata, meiotic recombination must be regulated at multiple levels: (1) DSB formation, to ensure that recombination is initiated on all homologs; (2) template choice, to favor inter-homolog interactions (as opposed to inter-sister recombination); (3) the crossover or noncrossover outcome, to produce at least one crossover per homolog pair; and (4) spatial-temporal integration with the other events of meiotic prophase, that is, homolog pairing, synapsis, and segregation.

Our current understanding of these regulatory processes is shown in Figure 5. The crossover or noncrossover outcome is thought to be assigned at an early step in the recombination pathway, at the transition into zygonema. At this stage, DSBs

that have been designated to become crossovers exchange DNA strands with the homologous chromosome to form first a single-end invasion (SEI) and then a double-Holliday Junction (dHJ; named after Robin Holliday who proposed the existence of these strand-exchange structures during homologous recombination; Figure 5). dHJs form during pachynema and are resolved toward the end of this stage, by a nick and ligation mechanism, to give crossovers. DSBs that are not designated as crossovers are repaired by a process called synthesis-dependent strand-annealing (SDSA), which involves first copying DNA sequences from the homologous chromosome and then annealing the two DSB ends to seal the break. SDSA does not appear to involve stable, long-lived strand-exchange intermediates like SEIs and dHJs.

Recombination-Independent Mechanisms of Homolog Pairing and Segregation

In most organisms, recombination-independent mechanisms make important contributions to homolog pairing and synapsis. In fission yeast, microtubules attach to the chromosome ends and vigorously drag the chromosomes back and forth, bringing them into alignment. Actin-based chromosome movements facilitate pairing and synapsis in other organisms. Some species, such as nematode worms and fruit flies, have evolved special chromosomal sites that allow homologs to pair

independently of recombination. In fact, in fruit flies, homologs are already paired in somatic cells prior to meiosis. A completely recombination-independent meiotic process is apparent in male fruit flies and female moths, in which homologs are segregated without the benefit of chiasmata. In the case of female moths, SCs are maintained until anaphase I and thereby appear to negate the need for chiasmata.

Meiosis and Human Disease

Defects in meiosis can lead to programmed cell death, reduced numbers of gametes, and reduced fertility. More subtle defects in meiotic chromosome segregation result in aneuploid gametes that either lack or contain an extra copy of a chromosome. The monosomic or trisomic zygotes that result from aneuploid gametes are generally inviable due to gene imbalances that are incompatible with development. Well-known exceptions are Down syndrome (trisomic for chromosome 21), Turner syndrome (monosomic chromosome X), and Klinefelter's syndrome (males with two X chromosomes). In humans, ~30% of pregnancy miscarriages are the result of meiotic segregation errors that arise, primarily, in the female germline. The frequency of aneuploid oocytes (and the ensuing risk of miscarriage and aneuploid offspring) increases dramatically with advancing maternal age. The so-called 'maternal-age effect' is thought to result from the deterioration of oocytes that are arrested in the dictyate stage, rendering them less capable of efficiently segregating chromosomes when meiosis resumes at the time of ovulation.

Glossary

Adrenocorticotropin ACTH, a 39-amino-acid peptide cleaved from proopiomelanocortin (POMC) in the anterior pituitary, that is secreted into the bloodstream and regulates the synthesis and release of the glucocorticoid class of steroid hormones.

Agouti proteins Along with agouti-related protein (AGRP), a family of small secreted proteins that bind to and antagonize melanocortin receptors.

Cachexia A condition associating anorexia, increased energy expenditure and lean body mass loss that accompanies chronic diseases.

Energy homeostasis The process by which the brain detects long-term energy reserves, stored in adipocytes in the form of fat, and regulates food intake and metabolic processes so as to keep reserves constant.

Melanocortin A peptide derived from the proopiomelanocortin gene containing a –His–Phe–Arg–Trp– motif within its sequence that binds to and activates one or more of a family of five melanocortin receptors.

Melanocyte A cell type populating skin and hair follicles that pigments hair and skin by secreting a variety of forms of melanin.

Tachyphylaxis A phenomenon characterizing a rapid decrease in drug response upon repeated doses.

The melanocortins are a family of peptides defined by their ability to modulate the activity of a family of five related G-protein-coupled receptors (GPCRs), called the ‘melanocortin receptors’ (MC1-R, also called the ‘melanocyte stimulating hormone receptor’; MC2-R, also called the ‘adrenocorticotropin receptor’; MC3-R; MC4-R; and MC5-R). The name is derived from the two original physiological activities identified for the family of peptides, stimulation of melanin synthesis and deposition, and stimulation of glucocorticoid synthesis and release by the adrenals. Four major melanocortin agonist peptides (α -melanocyte-stimulating hormone (MSH), β -MSH, γ -MSH, and adrenocorticotrophic hormone (ACTH)) are encoded by a single gene, the proopiomelanocortin (POMC) gene. Major sites of POMC gene expression include the pituitary, hypothalamus, brainstem, and skin. The melanocortin system is quite unique in that specific receptor antagonists, called ‘agouti’ and ‘agouti-related protein (AGRP)’, also exist. Together, these melanocortin agonists and antagonists regulate a remarkably diverse array of physiological processes, including the pigmentation of hair and skin, production of glucocorticoids, energy homeostasis, natriuresis, secretion of diverse exocrine gland products, and erectile function. A third agouti protein, AgRP2, has been discovered in teleosts, and appears to play a role in background color adaptation.

Melanocortin Ligands and Receptors

Elements of the mammalian melanocortin system are encoded by eight genes, the POMC gene, encoding the melanocortin peptide agonists, the five melanocortin receptor genes, and two genes, agouti and AGRP, that encode secreted melanocortin receptor antagonists. The melanocortin system appears to have developed with the evolution of vertebrates. While melanocortin-like

peptides can be found in invertebrates, the receptors appear first in vertebrate species. Most fish species contain all five melanocortin receptors. The lamprey genome, on the other hand, contains two melanocortin receptors, MCA, the likely precursor of the MC1 and MC2 receptor, and MCB, the likely precursor of the MC3, MC4, and MC5 receptors. The agouti and AgRP genes are not found in lampreys, and thus appear to be a later addition to the melanocortin system.

Peptide agonists are encoded within three different regions of the POMC preprohormone precursor. The POMC gene is expressed primarily in the anterior and intermediate lobes of the pituitary, the arcuate nucleus of the hypothalamus and the nucleus of the solitary tract of the brainstem, and in skin and a handful of peripheral sites where the peptides are thought to act in a paracrine or autocrine fashion. Melanocortin peptides are cleaved from three different regions of POMC to yield γ -MSH (amino terminal), ACTH and α -MSH (overlapping peptides from the central portion, and β -MSH (carboxy-terminal end) peptides. Specific patterns of cleavage occur in different tissues, so, for example, the 39-amino-acid peptide encoding ACTH is produced in the anterior pituitary by the peptidase PC1. A peptidase expressed in the intermediate lobe, PC2, makes a second cleavage to yield α -MSH, derived from the first 13 amino acids of ACTH. Melanocortin peptides derived from any of the three regions of POMC contain a His–Phe–Arg–Trp amino acid motif; this peptide motif is required for high affinity binding of these peptides to the melanocortin receptors.

In addition to peptide melanocortin agonists derived from POMC, two genes, agouti and AGRP, encode small secreted antagonists of the melanocortin receptors. Agouti is a 131-amino-acid protein with 10 disulfide-bonded cysteine residues related in structure to small peptide toxins like the conotoxins and plectotoxins, produced by cone snails and spiders,

respectively. Agouti is produced by hair follicle cells, where it acts on adjacent follicular melanocytes to antagonize the MC1-R and switch the cell from eumelanin (brown–black) to pheomelanin (yellow–red) pigment synthesis. AGRP, also 131 amino acids in length, shares sequence similarity with agouti in the cysteine-rich carboxyterminal domain, and is an endogenous antagonist of the MC3-R and MC4-R. AGRP is expressed in the adrenal gland and in the arcuate nucleus of the hypothalamus; in this latter site, AGRP is co-expressed with neuropeptide Y in a set of neurons adjacent but distinct from POMC arcuate neurons. In the brain, the AGRP gene is dramatically upregulated by fasting. The arcuate AgRP neurons are required for food intake, as specific ablation of these neurons results in cessation of food intake and, ultimately, death.

The melanocortin receptors, MC1-R through MC5-R, are encoded by a family of five independent genes; each receptor amino acid sequence is found in a single coding exon. The receptors are in the seven-membrane-spanning GPCR class, and all five receptors couple, via Gs, to activation of adenylyl cyclase. With the exception of the MC2-R, all of the melanocortin receptors bind multiple melanocortin peptide species. The MC2-R binds only the ACTH peptide, and the MC3-R is the only receptor that exhibits high affinity γ -MSH binding. Much of the physiological specificity of melanocortin peptide action derives from the unique tissue distribution of the five receptor subtypes (Table 1).

Pigmentation

The genetic study of coat colors led to the identification of over 60 genes involved in pigmentation. These genes encode proteins involved in all stages and aspects of the process by which melanocytes migrate from the neural crest, populate skin and hair follicles, and synthesize and secrete melanin or pigment granules. The biochemically complex melanin polymers can be divided into two classes, the yellow–red pheomelanins and brown–black eumelanins. The regulation of enzyme activities leading to these two pigment classes is termed the ‘eumelanin–pheomelanin switch’. Genetic studies of pigmentation in the mouse and a variety of other mammalian species led to the identification of two gene loci primarily involved in the regulation of the eumelanin/pheomelanin switch, *agouti* and

extension. The *extension* locus encodes the MSH receptor, or MC1-R, while *agouti* encodes an endogenous MC1-R antagonist expressed in skin and hair follicle. Mutations inactivating the MC1-R lead to yellow or red coat color, while mutations inactivating agouti lead to dark black coat colors. Loss-of-function mutations in the human MC1-R are responsible for approximately 80% of red hair color and type I skin pigmentation in humans. In many mammals in the wild, upregulation of agouti expression during a brief period of synthesis of a hair shaft leads to blockade of MC1-R activity, and results in deposition of a pheomelanin band along the otherwise darkly pigmented hair, known as the ‘wild-type agouti pigmentation pattern’ (Figure 1). In dogs, the *K* locus, encoding one of the endogenous anti-microbial β -defensin peptides, yields black coat color by blocking agouti action via a mechanism that has not yet been fully elucidated.

Adrenocortical Steroidogenesis

The ACTH receptor, or MC2-R, is expressed almost exclusively in the cortex of the adrenal glands, where it regulates synthesis and release of glucocorticoids in response to release of ACTH by the pituitary gland. ACTH also has long-term effects on the growth and differentiation of the cells of the adrenal cortex. ACTH is a 39-amino-acid melanocortin peptide cleaved from POMC in the anterior lobe of the pituitary. ACTH release, in turn, is regulated by production of corticotropin-releasing hormone, and hypothalamic releasing factor produced in response to a wide variety of stressors. These factors, in concert, constitute what is widely known as the ‘hypothalamic–pituitary–adrenal (HPA)’, or stress axis, which functions to allow organisms to adapt to internal and external challenges to homeostasis. Glucocorticoids serve many functions, but in general serve an adaptive role in coping with challenges to the organism by mobilizing carbohydrate energy stores and suppressing the immune system. Glucocorticoids are also essential for development. A rare syndrome of ACTH resistance resulting from loss-of-function mutations in the MC2-R, known as familial ACTH resistance or familial glucocorticoid deficiency (FGD), often presents with neonatal hypoglycemia, hepatitis, hyperpigmentation of skin due to elevated ACTH and, in some cases, severe septic events. Approximately 20% of FGD cases result

Table 1 The melanocortin receptors and their known functions

Receptor subtype	Site of action	Ligand	Biological function
MC1-R	Melanocyte	α -MSH = β -MSH = ACTH > γ -MSH > ACTH _{4–10} Antagonists – Agouti (IC ₅₀ ~ 1 nM)	Pigmentation
MC2-R	Adrenal cortex	ACTH	Steroidogenesis
MC3-R	CNS, stomach, duodenum, placenta, and pancreas	γ ₁ -MSH = γ ₂ -MSH = α -MSH = β -MSH = ACTH Antagonists – AGRP (~2 nM)	Energy homeostasis; natriuresis
MC4-R	Adult CNS, spinal cord, fetal brain, spinal cord, and autonomic nervous system	α -MSH (EC ₅₀ = 0.2–1.5 nM) = β -MSH = ACTH > ACTH _{4–10} = γ -MSH > ACTH _{4–10} Antagonists – AGRP (IC ₅₀ ~ 2 nM)	Energy homeostasis
MC5-R	Exocrine glands	α -MSH > β -MSH = ACTH > γ -MSH > ACTH _{4–10}	Synthesis and secretion of exocrine gland products

Figure 1 Integration of long-term adipostatic signals and acute satiety signals by the central melanocortin system. Blue: nuclei containing POMC neurons and AGRP neurons; yellow: nuclei containing MC4-R neurons that may serve to integrate adipostatic and satiety signals; red arrows: adipostatic signaling; green arrows: satiety signaling; BST, bed nucleus of the stria terminalis; CEA, central nucleus of the amygdala; PVN, paraventricular nucleus of the hypothalamus; LH, lateral hypothalamic area; LPB, lateral parabrachial nucleus; AP, area postrema; DMV, dorsal motor nucleus of the vagus. from mutations in melanocortin receptor accessory protein (MRAP), a transmembrane protein that is essential for both transport of the MC2-R to the plasma membrane and binding of ACTH by the receptor.

Energy Homeostasis and Other Central Nervous System Actions

The cloning of the MC1-R (MSH-R) and MC2-R (ACTH-R) genes led to the identification of three additional GPCRs that were highly related in primary amino acid sequence and also were high-affinity receptors for melanocortin peptides. Since these receptors had, at the time, unknown physiological roles, they were termed 'MC3-R', 'MC4-R', and 'MC5-R'. Remarkably, a novel mutation in the agouti gene that caused not only yellow coat color but also an obesity syndrome in the mouse ultimately led to the discovery that the MC3-R and MC4-R play a role in the central control of energy homeostasis. The lethal yellow allele of agouti results from a promoter rearrangement that causes ubiquitous expression of the agouti gene, in contrast to its normal expression limited to the hair follicle, where it normally serves to block eumelanin synthesis. Aberrant expression of agouti in the brain results in blockade of the brain MC4-R, resulting in the agouti obesity syndrome. Discovery of AGRP identified an endogenous hypothalamic antagonist of the central MC3-R and MC4-R that has a physiological role in the regulation of the central melanocortin system. Pharmacological blockade of the MC4-R, deletion of the gene, or deletion of the ligand-encoding gene, POMC, also reproduce the agouti obesity syndrome. In humans, haploinsufficiency of the MC4-R, that is loss-of-function or hypomorphic mutations in one allele, appear to be responsible for as much as 5% of cases of severe early onset obesity, making the MC4-R the most common genetic cause of severe obesity known. Less is known regarding the MC3-R; however, it is expressed in a majority of arcuate POMC neurons where it

appears to function as an inhibitory autoreceptor. Deletion of the MC3-R also causes a mild obesity syndrome associated with Cushing's syndrome-like symptoms.

The central melanocortin system is defined as the hypothalamic POMC and AGRP neurons that originate in the arcuate nucleus, brainstem POMC neurons originating in the nucleus of the solitary tract, and their target MC3-R- and MC4-R-expressing neurons, found throughout the central nervous system (CNS), in approximately 200 discrete locations (Figure 1). Central administration of melanocortin agonists both inhibits food intake and increases energy expenditure. These data, and the fact that blockade of MC4-R signaling causes obesity, argue that the POMC neurons tonically inhibit food intake and energy storage. The melanocortin system does this through effects on both food intake and on autonomic outflow to metabolically important tissues in the periphery. POMC and AGRP neurons express receptors for the adipostatic hormone leptin, and are regulated as well by a network of leptin-receptor-expressing GABAergic neurons, and play an important role in sensing and responding to the leptin signal from adipose tissue that informs the brain of long-term energy stores. POMC neurons also appear to be important for sensing and responding to acute satiety and hunger signals. The central melanocortin system affects autonomic outflow to a wide variety of tissues; melanocortins also have effects on glucose homeostasis, blood pressure, heart rate, natriuresis, inflammatory response, and the male erectile response. Therapeutic applications of melanocortins may include obesity, diabetes, cachexia, and erectile dysfunction.

Exocrine Gland Function and Other Peripheral Actions

MC5-R is expressed at high levels in a diverse array of exocrine glands, such as the sebaceous, lacrimal, preputial, and Harderian glands of the mouse. The receptor appears to stimulate the

production and release of exocrine gland products from these tissues. For example, a knockout mouse specifically lacking the MC5-R gene was found to produce reduced amounts of certain lipids normally secreted by sebaceous glands onto the coat of the animal, thus reducing the ability of the coat to repel water. Male MC5-R knockout mice also exhibit a defect in initiating aggressive behavior relative to their wild-type counterparts, which has been attributed to defects in the secretion of pheromones by glands like the preputial, known to express high levels of the receptor. Little is known regarding the actual physiological roles of the MC5-R in the various exocrine tissues. For example, it is not clear whether the source of ligand for the MC5-R is the predominant serum melanocortin, ACTH, or whether this receptor is regulated by yet uncharacterized paracrine sources of POMC. If the former is the case, the system would provide a mechanism for stress-induced stimulation of exocrine gland function. Suppression of sebaceous gland function in acne by MC5-R antagonism is a potential therapeutic utility of this receptor.

The MC3-R is also expressed in a handful of peripheral tissues, although little is known regarding its actions. The MC3-R and γ -MSH appear to be involved in the regulation of natriuresis; the reflex natriuresis that occurs after unilateral nephrectomy requires the MC3-R, and MC3-R knockout mice exhibit salt-sensitive hypertension.

Synthetic Ligands and Drug Discovery Efforts

The MC4-R has attracted the attention of the pharmaceutical industry, given possible applications of agonist drugs as potential obesity and sexual dysfunction treatments, and the application of antagonists for the treatment of cachexia, a disease condition commonly associated with chronic diseases such as cancer, AIDS, and cardiac or renal failure.

The first compounds to be discovered were modified peptides based on the -His-Phe-Arg-Trp- motif of the endogenous melanocortin ligands such as α -MSH. The first important agonist to be discovered, melanotan-II (MT-II), is a heptapeptide that was cyclized for increased half-life. This compound is around 100-fold more potent than α -MSH and is equally potent for MC3R and MC4R. This molecule was successfully shown to be erectogenic and to decrease food intake in both animals and humans. Based on a similar cyclic structure, SHU9119, a potent competitive antagonist was developed. This antagonist was shown to be able to restore food intake in cachexia models in the animal. Similar results could be obtained with the physiological inverse agonist AgRP.

Bremelanotide, another cyclic agonist, entered clinical trials to treat sexual dysfunction. In the recent years, the first non-peptidic small melanocortin molecules were discovered on the basis of structure-activity relationships focusing on the MSH pharmacophore or through large pharmacological drug screens. From these studies, tetrahydroisoquinoline (THIQ), a potent selective MC4R agonist, was the first nonpeptidic compound to be discovered. Overall, these nonpeptidic compounds present advantages regarding their pharmacokinetic properties as well as being orally available compared to their peptidic counterparts.

Therapeutic Potential

Antiobesity

The development of melanocortin agonists looked initially very promising as antiobesity drugs. However, the long-term administration of the agonist such as MT-II only induces a transient decrease in food intake that resolves within days. The exact explanation of this phenomenon referred to as 'tachyphylaxis' remains unknown. In this regard, the benefits of a long-term treatment based on melanocortin agonist drugs might potentially be affected. The very first clinical trials reported so far failed due to efficacy problems or side effects, such as an increase in blood pressure.

Sexual dysfunction

The implication of the melanocortin system in penile erection was first discovered with the agonist MT-II. These effects are believed to be centrally mediated. Bremelanotide is considered as a promising initiator of erection tested independently or together with the phosphodiesterase type 5 (PDE5) inhibitor sildenafil, and also exhibited unacceptable pressor activity.

Cachexia

Many pharmacological approaches based on the melanocortin antagonist SHU9119 or the endogenous inverse agonist AgRP successfully improved the phenotype of different acute (lipopolysaccharide injection) or chronic cachexigenic murine models (cancer induced or nephrectomy). The implication of the melanocortin system in the pathophysiology of cachexia was further confirmed by means of the genetic Mc4r knockout mice. These observations provide a strong rationale to develop small antagonist molecules selective for MC4R. So far, these molecules still remain at early preclinical stages.

Membrane-Associated Energy Transduction in Bacteria and Archaea

Glossary

Archaea The prokaryotic domain consists of two branches of the phylogenetic tree of life, one occupied by the bacterial domain and the other by the archaeal domain. The latter splits into the euryarchaeota and the crenarchaeota. Both archaeal sub-branches are host to many extremophilic genera. The methanogens belong to the euryarchaeota, the thermoacidophiles with a few exceptions to the crenarchaeota.

Chemolithotrophs Prokaryotes assimilating carbon dioxide as sole carbon source and extracting energy from inorganic redoxreactions (in contrast to organotrophs that use reduced organic substrates as their carbon and/or nitrogen source).

Chromophore Usually, a colored organic molecule bound to a protein and functioning as a cofactor in catalysis. Hemes are chromophores of cytochromes and host Fe ions in the core of a porphyrin ring; other tetrapyrrol derivatives such as chlorophyll host Mg or Co. Chlorophylls and carotenoids in reaction centers or

antenna systems, and retinal in rhodopsins, are light-energy transducers.

Endosymbiosis Uptake of an originally independent free-living organism into cells of a host organism, where it can reproduce under the control of the host organism and share metabolic functions (the energy-transducing organelles of eukaryotes originated by permanent transfer of genetic material from the endosymbiont to the host genome).

Prokaryotes Unicellular microbes without a cell nucleus (in contrast to the eukaryotes that are located on a distinct branch of the universal phylogenetic tree of life, the eukaryotic domain).

Thermoacidophiles Prokaryotes with a lifestyle adapted to hyperthermophilic conditions (75–110 °C) as well as to extremely low environmental pH (3.5–0.5). Most of them belong to the archaea.

Vacuoles Membrane-encapsulated compartments within eukaryotic cells, in most cases, filled with liquid of low pH; their membrane contains an adenosine triphosphate (ATP)-driven proton pump, the V-type ATPase.

Archaea and bacteria represent the two prokaryotic branches of the universal tree of life. Their plasma membranes host protein complexes specialized in primary and secondary energy-transducing mechanisms. Common to bacteria and archaea is the underlying principle of primary energy conservation, the chemiosmotic mechanism generating an electrochemical potential of ions across the membrane on expense of the energy derived from membrane-associated fermentative, redox- or light-driven processes. In evolution, two of these, oxygen respiration and oxygenic photosynthesis, were transferred to eukaryotes by endosymbiotic uptake of putative ancient bacteria, the precursors of mitochondria and chloroplasts. Archaea differ from bacteria not only by genetic and taxonomic markers, membrane structure, specialized metabolic functions, and archaetypical coenzymes, but also by their extremophilic lifestyles regarding thermo-, pH-, and salinity-tolerance. Several energy-transducing processes are confined to the archaeal domain such as methanogenesis and rhodopsin-dependent photosynthesis. Chlorophyll-dependent photosynthesis does not exist in the archaeal domain. Secondary membrane-associated energy transduction such as the synthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and various active transport systems are consumers of the primarily generated electrochemical ion gradient. The ions that couple primary and secondary energy transduction are predominantly hydrogen ions; in several bacteria and archaea sodium ions are also used.

Membranes

The matrix of polar lipids in plasma membranes serves as the environment for associated and membrane-spanning proteins. In bacteria, glycerol diester phospho- and glycolipids form a liquid-crystalline bilayer into which the energy-transducing membrane-protein complexes are inserted. The hydrophobic properties and fluidity of the core are determined by the fatty acid hydrocarbon chains; the permeability properties are additionally determined by the polar head groups. The lipid profile can serve as a taxonomic marker. Archaea, in contrast, contain unique lipids consisting of derivatives of diphytanylglycerol diethers and of di-biphytanyl-diglycerol-tetraethers. Consistently, besides bilayer structures, these membranes are composed of membrane-spanning lipid monolayers conferring extremely high stability, especially to the hyperthermophilic genera of the archaeal domain. The diether- and tetraether-derived lipids include phospholipids, glycolipids, and sulfoglycolipids. Generally, these lipids are glycosylated with the carbohydrate groups facing the plasma membrane outside. The unique lipid composition clearly delineates the archaea from all other organisms. Also, the cell envelopes of archaea are distinct from those of bacteria. Murein and lipopolysaccharide-containing outer membranes are not found in archaea. The quasi-crystalline surface layers of archaea are high-molecular-weight glycoproteins and have mainly form-stabilizing function and, in most cases, are the only envelope layer outside the plasma membrane.

Energy-Transducing Functions

Membrane-associated energy transduction proceeds by linking an exergonic process catalyzed by a membrane-residing enzyme (or protein complex) to the simultaneous vectorial translocation of charge (electrons or ions) across this membrane by the same enzyme. This principle is common to bacteria and archaea (Figure 1). Typical processes can be metabolic substrate conversions such as redox reactions or decarboxylation, respiratory electron transport from a low-potential donor to a high-potential acceptor (respiratory chains), or the decay from an energized state of a molecule generated by absorption of light to the low-energy ground state.

Figure 1 Schematic illustration of energy-conserving principles used by bacteria and archaea for the generation of an electrochemical potential of ions ($\Delta\mu\text{Na}^+$ or $\Delta\mu\text{H}^+$) across their plasma membrane. (a) Symbolizes $\Delta\mu\text{H}^+$ generation by scalar or so-called chemical protons consumed or liberated on opposite sides of the membrane; only electrons are transduced through the membrane. (b,c) Illustrate pumps: (b) functions via the intermediary quinol pool (x), (c) integrates pumping and electron transport within the same protein module like cytochrome-*c* oxidases; (d) symbolizes the universal ATP synthetase; its vectorial action and orientation is consistently opposite to that of the primary pumps.

Fermentation

Fermentations are anaerobic redox processes in which ATP is usually generated by substrate-level phosphorylation. In some special cases, partial reactions of fermentative pathways are catalyzed by membrane-residing enzymes, and the free-energy change of the reaction is coupled to the generation of an electrochemical-ion gradient. Examples are the biotin-dependent methylmalonyl-coenzyme A (CoA) decarboxylase of *Propionigenium modestum*, the oxaloacetate decarboxylase involved in citrate fermentation, or the glutamyl-CoA decarboxylase involved in glutamate fermentation – they generate a $\Delta\mu\text{Na}^+$. By means of H^+/Na^+ exchange transporters, the sodium gradient can be coupled to a proton gradient, or the $\Delta\mu\text{Na}^+$ can directly drive ATP synthesis by a Na^+ -translocating ATP synthetase. In methanogenic archaea, methyl-group transfer from an N atom to an SH group drives a sodium pump and also generates a $\Delta\mu\text{Na}^+$. The above examples demonstrate that in anaerobic fermentations also nonredox reactions can play an important role in membrane-associated energy transduction.

Anaerobic Respiration

Many organotrophic and chemolithotrophic bacteria and archaea can conserve energy by means of membrane-residing electron transport chains employing terminal acceptors other than oxygen. This group of obligately or facultatively anaerobic microbes uses electron acceptors such as nitrate, nitrite, fumarate, sulfur, ferric ion, carbon dioxide, sulfate, or even organic chlorocompounds for oxidation of organic molecules or hydrogen. Energy is conserved as a $\Delta\mu\text{H}^+$. Example reactions are given in Table 1.

The block on top gives examples for electron-accepting reactions in anaerobic respirations, the lower block exemplifies electron-donor reactions used by organotrophic and chemolithotrophic oxygen respiration. $[\text{H}]_2\text{-X}$ symbolizes an organic hydrogen-donating molecule, for example, reduced nicotinamide-adenine-dinucleotide (NADH) or succinate.

Denitrification

Denitrification is a typical example of anaerobic respiration and is found in over 40 genera; in archaea only in some

Table 1 Standard free energy changes of anaerobic and aerobic respiratory reactions

extreme halophiles. However, nitrate is reduced in four steps to $\text{N}_2 \rightarrow \text{NO}_2^- \rightarrow \text{NO} \rightarrow \text{N}_2\text{O} \rightarrow \text{N}_2$. The enzymes are integrated into the plasma membrane or located in the periplasm. Oxygen represses their synthesis. Nitrate reductase is a molybdopterin dinucleotide-containing enzyme associated with an iron-sulfur protein (four FeS clusters) and a membrane spanning *b*-type cytochrome. Energy from NO_3^- reduction is conserved by release of protons from the reductant, ubiquinone, or menaquinone, at the membrane outside, whereas protons for water formation are taken up from the cytosol. NO reductase displays analogy to heme/Cu oxidases but hosts Fe instead of Cu in the binuclear reaction center; in contrast to the latter, it does not pump protons. Denitrifying pathways are widespread in Gram-negative proteobacteria (e.g., *Paracoccus*, *Alcaligenes*, *Pseudomonas*, and *Thiobacillus*). Associated with denitrification is ammonification, which saves NH_4^+ by reduction of NO_2^- with NAD(P)H. Ammonification is a cytosolic process catalyzed by a siroheme/[4Fe4S]-containing enzyme.

Fumarate Respiration

In *Wolinella*, nitrate reduction can be achieved with molecular hydrogen or with formate as electron donors. It involves fumarate respiration (Figure 2), as an alternative mechanism to generate a proton-motive force. H^+ is released at the outer side of the membrane by oxidation of hydrogen or formate, whereas proton uptake and reduction of fumarate occur at the inner side. The dehydrogenases as electron donors and the fumarate reductase as acceptor are interacting via *b*-type cytochromes and the menaquinone pool in the membrane ($E'_0 = -100$ mV). The reduction of fumarate to succinate is catalyzed by an enzyme similar to nitrate reductase, but molybdopterin is replaced by flavine-adenine-dinucleotide (FAD). The enzyme is structurally and evolutionarily related closely to succinate dehydrogenases of aerobic organisms which catalyze the reverse reaction using ubiquinone

($E'_0 = +60$ mV), or in thermoacidophilic archaea *Caldariella* quinone ($E'_0 = +106$ mV), as primary electron acceptor.

Sulfur Respiration

Some bacteria and archaea perform sulfur respiration – *Wolinella succinogenes* is an example. Instead of insoluble elemental sulfur polysulfide (S-S_n^-) serves as electron acceptor. The electron transport chain involves three membrane-residing enzymes with their substrate-binding sites facing the periplasm: formate dehydrogenase or hydrogenase, and polysulfide reductase. In contrast to fumarate respiration, a quinone is not involved in electron transfer. The reduction of sulfur to H_2S is coupled to generation of $\Delta\mu\text{H}^+$ at a low H^+/e^- ratio by a hitherto unknown mechanism.

Ferric Ion Reduction

Members of the genera *Clostridium*, *Escherichia*, and *Bacillus*, among others, are able to reduce ferric to ferrous ions. It has not been shown unequivocally that the reaction is coupled to energy conservation. Although the couple $\text{Fe}^{3+/2+}$ has a high redox potential ($E'_0 = +770$ mV) similar to oxygen, organisms using Fe^{3+} as terminal electron acceptor have to cope with its extreme insolubility, except in a strongly acidic environment.

Oxygen Respiration

Aerobic Organotrophs

Oxygen is a superior electron acceptor for aerobic microbes that use reduced substrates or even molecular hydrogen as donors of reducing equivalents. Organotrophs deliver electrons into a respiratory chain (Figure 3) via ubi- or menaquinone-reducing membrane-anchored or integral membrane protein complexes. A major complex is the

Figure 2 Scheme of an anaerobic respiration. Fumarate respiration is taken as an example with two possible electron-donating systems. The type of energy conservation corresponds to principle A in Figure 1. MQ, menaquinone; P, periplasm; C, cytosol.

Figure 3 Illustration of the diversity of energy-transducing membrane systems in bacteria and archaea. All boxed or encircled components are membrane-integral or membrane-associated. All red boxes are proton pumps acting according to principles (b) and (c) of Figure 1. The scheme depicts the situation in *P. denitrificans*. The shaded block from left to right symbolizes a regular and complete aerobic respiratory chain as present, for example, in purple bacteria and also in eukaryotic mitochondria. The linear arrows indicate the direction of electron flux between donor and acceptor complexes or compounds. The symbols aa₃, ba₃, and bo₃ in the box quinoloxidases indicate the species-dependent variability of observed heme-compositions; calQ (caldariella quinone) applies to some archaea, as does the blue-Cu protein instead of c-type cytochromes. SDH, succinate dehydrogenase, complex II.

FMN-dependent type-I NADH dehydrogenase (complex I), composed of 14 different polypeptides (e.g., *Paracoccus* and *Escherichia coli*). It couples the translocation of (probably four) protons to the reduction of quinone and consists of a peripheral substrate oxidizing subcomplex facing the cytosol, a membrane integral transducer subcomplex with several FeS centers, and a receiver subcomplex transferring electrons to the quinone. Alternatively, in many bacteria and in archaea, type-II NADH dehydrogenases are found; these have less complex composition and cannot couple ion translocation to substrate oxidation. Several alkaline-adapted bacteria couple the translocation of Na⁺ instead of protons to NADH oxidation. As another quinone-reductase succinate dehydrogenase (complex-II) is found in the plasma membranes of all aerobic microbes. The small change in free energy of this reaction is insufficient to drive energy-conserving ion translocation. The reoxidation of reduced quinones is either catalyzed directly by heme/Cu-type quinol oxidases as, for example, in *E. coli*, *Paracoccus denitrificans*, and *Rhodobacter sphaeroides*, or by a second energy-conserving module of respiratory chains, the bc₁ complex (complex-III). The essential redox catalysts of this module are an [2Fe₂S] iron-sulfur protein (Rieske protein), a diheme b-type cytochrome, and a c-type cytochrome c₁. Complex-III couples the stepwise reoxidation of QH₂ to the transport of 2H⁺ across the membrane for each electron transduced to cytochrome c₁. The complex reaction mechanism is known as Q-cycle. The mobile redox carrier cytochrome c associated with the outer surface of the plasma membrane accepts electrons from cytochrome c₁ and serves as the connector to the terminal oxidase module, the heme/Cu-type cytochrome c oxidase (⇒). All oxygen-reducing heme/Cu oxidases are proton pumps. The path of electrons from NADH to oxygen can thus conserve the energy equivalent to 12H⁺ pumped across the membrane

per [H₂]. Depending on the genetic disposition, either one of the energy-transducing complexes can be missing, except a terminal oxidase. The modular structure of microbial respiratory chains allows a variety of special adaptations. Besides an aerobic respiratory chain, all modules for denitrification and even several terminal oxidases can be present in parallel (e.g., Figure 3); their individual contribution to energy transduction is usually regulated via the expression of the respective genes in response to nutritional and environmental conditions.

Aerobic Chemolithotrophs

A large variety of bacteria, the chemolithotrophs, can derive energy from oxidation of inorganic electron donors such as hydrogen, carbon monoxide, sulfur and nitrogen compounds, or divalent cations (e.g., Fe²⁺ and Mn²⁺). Many of these use molecular oxygen as oxidant. The mechanisms of energy transduction in chemolithotrophs are essentially the same as in organotrophs, that is, the electrons are channeled into a cytochrome chain and flow down to the terminal oxidase enabling a number of proton-translocating redox loops. Examples are given in Table 1. The acidophile *Thiobacillus ferrooxidans* uses a periplasmic Fe²⁺ oxidase transferring electrons via cytochrome c and the Cu-protein rusticyanin to a heme/Cu-terminal oxidase, which reduces oxygen on the plasma membrane inside. The reaction generates a proton-motive force by scalar consumption of H⁺ on the inside in addition to proton pumping by the aa₃-type terminal oxidase. So-called Knallgas bacteria comprising a large group of Gram-negative and Gram-positive bacteria, which can oxidize molecular hydrogen. Essential for the mechanism is a Ni-Fe hydrogenase dimer (e.g., in *Alcaligenes eutrophus*) in the cytoplasmic

membrane. It transfers electrons from hydrogen via the bimetallic reaction center, several Fe–S clusters, and a *b*-type cytochrome to the respiratory electron transport chain. By this process, scalar protons are produced outside in addition to protons pumped by the respiratory chain. Several Knallgas bacteria contain a second, cytoplasmic hydrogenase which is used for the reduction of NAD^+ via FMN by an enzyme with homology to NADH:ubiquinone oxidoreductase (complex-I).

Phototrophic Bacteria

The utilization of light by cyanobacteria, phototrophic purple, and green bacteria follows the same principles as in algae and higher plants. Also the light-absorbing pigments, other cofactors, and their hosting membrane proteins are essentially similar. Both, oxygenic and anoxygenic photosynthesis, are found; the latter is restricted to purple, green, and heliobacteria.

Pigments of Energy Transducers

Absorption of light energy and transduction of energized states is mediated by antenna complexes. These contain the cyclic tetrapyrrol derivatives chlorophyll and bacteriochlorophyll, carotenoids, and in cyanobacteria open-chain tetrapyrrols (phycobillins). The conjugated polyene compounds absorb light from the near-ultraviolet (UV) to the near-infrared (IR) and are noncovalently bound to membrane-integral and membrane-associated proteins in arrays. They transduce the excited state to the reaction centers (RCs) proper. The ratio is about 25–30 mol antenna chlorophyll per mol RC. In purple bacteria and heliobacteria (e.g., *Rhodobacter*, *Rhodospseudomonas*, *Chromatium*, and *Heliobacillus*), the antenna complexes are integrated within the cytoplasmic membrane. In green bacteria (e.g., *Chlorobium* and *Chloroflexus*), the antenna complexes are organized as chlorosomes, that is, vesicles attached to the inner side of the plasma membrane.

Anoxygenic Photosynthesis

Anoxygenic photosynthesis produces an electrochemical proton gradient across the membrane which drives ATP synthesis and other energy-consuming processes. Excitation energy is transferred from antennas to the RC within ~ 50 ps. In the RC, the energy is utilized to generate a charge separation ($\Delta\psi$) across the membrane. It occurs by electron transfer between the primary donor, a special pair of chlorophylls, localized toward the cytosolic side of the membrane and secondary acceptors at the opposite side. These can be quinones (type-II RC) or Fe–S clusters (type-I RC). From there the electrons flow back to cytochrome c_2 and the special pair via a quinone pool and through the bc_1 complex, as it is also used for respiratory energy conservation; a $\Delta\mu\text{H}^+$ is produced. Thus, anoxygenic photosynthesis can occur as a cyclic process. Production of reducing equivalents is not coupled to anoxygenic photosynthesis. In facultatively phototrophic/chemotrophic bacteria (*Rhodobacter* and *Rhodospirillum*), photosynthesis and respiration are competing for the bc_1 complex depending on the environmental conditions (oxygen tension and light intensity).

Oxygenic Photosynthesis

Cyanobacteria (*Synechococcus*, *Synechocystis*, and *Anacystis*) perform oxygenic photosynthesis. It employs two photosystems in sequence in its membrane (PS-I, PS-II). PS-I is essentially equivalent to the RC of anoxygenic phototrophic bacteria but channels the electrons to ferredoxin as terminal acceptor. Ferredoxin serves as reductant for NADP^+ , thus generating reducing equivalents for the cell. The reaction center PS-II is an H_2O :plastoquinone oxidoreductase and couples the reduction of the primary e^- -donor, the special pair of chlorophylls, to the oxidation of water by a Mn-enzyme associated with PS-II at the periplasmic surface. The water-splitting Mn-enzyme liberates molecular oxygen and H^+ . The reducing equivalents are passed on to PS-I via the plastoquinone quinone pool, the b_6f -complex, and the Cu-protein plastocyanin. The b_6f -complex is functionally and structurally analogous to the bc_1 complex. It is composed of a diheme cytochrome *b*, a Rieske Fe–S protein, and the mono-heme cytochrome *f*. b_6f acts as a proton pump performing a Q-cycle ($\Rightarrow$). The photosynthetic apparatus of cyanobacteria is localized in thylacoids; the antenna systems are organized as phycobilisomes attached to the thylacoid membranes. These structures largely resemble the structure of eukaryotic organelles. Also, respiratory enzymes (NADH dehydrogenase and cytochrome *c* oxidase) are localized in the thylacoid and partially also in the plasma membrane of cyanobacteria.

Special Mechanisms in Archaeal Energy Transduction

Methanogenesis from one- or two-carbon atom compounds and light-driven energy conservation by bacteriorhodopsins (BR) are mechanisms restricted to archaea. Methanogens comprise the genera *Methanosarcina*, *Methanobolus*, *Methanobacterium*, *Methanotrix*, *Methanothermus*, *Methanococcus*, and others among about 50 known species. Examples for the best-investigated genera of extreme halophilic archaea are *Halobacterium*, *Haloferax*, *Haloarcula*, *Halococcus*, and *Natronomonas*.

Methanogenesis

Methanogenesis is a reductive process under strictly anaerobic conditions. It involves reduction of C_1 compounds (CO_2 , CO , CH_3OH , and CH_3NH_2) mainly by H_2 , and also the disproportionation of acetate, formate, or methanol. Many of the methanogenic archaea are extremely thermophilic (growth at $\approx 100^\circ\text{C}$). For example, the change in free energy of the reaction $\text{CO}_2 + 4\text{H}_2 \Rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$ is $\Delta G = -131 \text{ kJ mol}^{-1}$ and is comparable to CH_4 formation from other sources; that of acetate disproportionation is only -36 kJ mol^{-1} . Both reactions can drive chemiosmotic ATP synthesis by linking membrane-associated partial reactions to generation of ion gradients ($\Delta\mu\text{H}^+$ and $\Delta\mu\text{Na}^+$). The reactions involve unusual coenzymes, not found in bacteria or eukaryotic organisms. These are the fluorescent 5-deazaflavin F_{420} , methanofuran, methanopterin (H_4MPT), coenzyme-M (mercaptoethanesulfonate), a Ni-tetrapyrrole F_{430} , 5-hydroxybenzimidazolyl-cobamide, and methanophenazine as a substitute for membrane-residing quinones. For details of pathways the reader is referred to

Figure 4 (a) Illustration of chemiosmotic energy conservation in methanogenic archaea. The example combines mechanisms (b) and (c) of Figure 1. P, periplasmic space; M, membrane; C, cytosol; MP, methanophenazine; CoM, coenzyme M. (b) Energy transduction by a non-edox reaction in archaeal methanogenesis. The sodium pump is driven by the energy change of the transmethylation reaction. H_4 -MPT, tetrahydro-methanopterin. The mechanism is thought to involve conformational coupling between the group-transferring and the ion-transferring modules; similar mechanisms apply to the sodium pumps driven by decarboxylation reactions.

specialized publications. Important for membrane-associated energy transduction are electron transport chains involved in methanogenesis, as illustrated in Figure 4. The ion-translocating redox chains involve hetero-disulfide reductase, two *b*-type cytochromes, methanophenazine, and Ni-hydrogenase or another donor of reducing equivalents. Redox cycling of methanophenazine with asymmetric uptake and release of protons can act as a proton pump with $H^+/e^- = 1$. Hydrogen can

also be provided from ferredoxin:methanophenazine oxidoreductase, or from F_{420} dehydrogenase, depending on the individual organisms and the C_1 carbon source used for methanogenesis. Whether the latter functions as proton pump is under debate; the observed total H^+/e^- ratios of 3–4, are higher than calculated for the methanophenazine cycle alone. Hydrogenases and F_{420} dehydrogenase display structural similarities to proton-translocating respiratory NADH dehydrogenases and are bearing subunits with several $[Fe-S]$ clusters. Also, heterodisulfide reductase contains two $[4Fe-4S]$ clusters. Apart from proton-motive electron transport chains, all methanogens have a primary Na^+ pump, the membrane integral methyl- H_4 MPT:CoM-methyltransferase. This enzyme contains the above-mentioned cobamide cofactor and a $[4Fe-4S]$ cluster. The reaction proceeds in two steps: first, the transfer of the methyl group to the corrin cofactor, second, methyltransfer to the cytosolic cofactor HS-Coenzyme M. Sodium pumping is associated with the second partial reaction producing a Na^+ gradient equivalent to a -60 mV membrane potential. The sodium pump consists of six to eight polypeptides (species dependent). The central pathway of methanogenesis is reversible. Accordingly, the enzyme acts as a sodium pump during methanogenesis from CO_2 or acetate but drives the reverse reaction by means of a sodium potential in methanogenesis from methyl group containing C_1 compounds.

Utilization of Light

Photosynthetic apparatuses as found in phototrophic bacteria and eukaryotes do not exist in archaea. However, the aerobic extreme halophiles like *H. salinarum* can synthesize a light-driven proton pump under conditions of low-oxygen tension composed of a single integral-membrane protein BR. BR spans the membrane with seven α -helical domains enclosing the chromophore retinal, which is bound as protonated Schiff's base to a lysine in the hydrophobic core of the protein. Absorption of light induces an all-*trans* to 13-*cis* isomerization of retinal accompanied by a deprotonation of the Schiff's base with concomitant release of the proton on the periplasmic membrane surface via a channel delineated by a series of protonable amino acid residues and water molecules. The light-triggered reaction is accompanied by conformational changes of the protein and initiates a photocycle of the chromophore that relaxes through five to six consecutive steps to the all-*trans* ground state. In that phase reprotonation of the Schiff's base from the cytosolic side of the plasma membrane is attained. The proton pumping power stroke corresponds to about -50 kJ mol $^{-1}$ and can generate a proton-motive potential of about 300 mV. The light-induced proton gradient $\Delta\mu H^+$ can drive ATP synthesis, the flagellar motor, or a Na^+/H^+ antiporter to drive sodium out of the cell. Besides BR, three other archaeal rhodopsins were found. Halorhodopsin (HR) has a similar structure but acts as an inwardly directed chloride pump. The two other so-called sensory rhodopsins (SR 1 + 2) are photoreceptors that trigger the flagellar motor (phototactic/photophobic) via conformational coupling of membrane-associated transducer units (Figure 5). As such they are basic models for the large variety of seven-helix membrane receptors. All four archaeal rhodopsins have striking similarity regarding

Figure 5 Illustration of energy transduction and sensory functions of rhodopsins in the extreme halophilic archaea. BR, bacteriorhodopsin; HR, halorhodopsin; SR1 and SR2, sensory rhodopsins. Only BR and HR are ion pumps. The homodimeric transducer complexes Tr1, 2 are conformationally coupled to SR1, SR2, and transfer the conformational signal via their cytoplasmatic domains to a signaling cascade controlling the rotational direction of the flagella motor. The orientation of vectorial reactions is indicated with 'in' symbolizing the cytosolic side of the plasma membrane.

protein structure, the retinal chromophore and its photocycle. However, the ion-transducing BR and HR perform fast photocycles in the millisecond range, whereas SR 1 + 2 are comparatively slow (~100 ms).

Respiratory Complexes

The euryarchaeota *Halobacteria*, *Thermoplasma*, and many species of the crenarchaeota comprising genera as *Sulfolobus*, *Acidianus*, *Metallosphaera*, or *Pyrobaculum* are obligate or facultative aerobes. Their respiratory systems essentially resemble modular components of respiratory chains as found in oxygen-respiring bacteria. A significant difference is the lack of a proton translocating NADH:quinol oxidoreductase. Instead, type-II NADH dehydrogenases were found, whereas complex-II analogous succinate dehydrogenases are present in all aerobic archaea. Two groups of enzymes can be distinguished: one group resembles the properties of SDHs from bacteria and mitochondria, and the other represents a novel class with unusual iron-sulfur clusters, as well as additional ones in a subunit with homology to methanobacterial heterodisulfide reductase, suggesting a novel electron pathway to the quinone pool. In *Halobacteria*, menaquinone and ubiquinone function as membrane-integral electron acceptors; in *Thermoplasma* and thermoacidophilic crenarchaeota like *Sulfolobales*, these are replaced by caldariella quinone and a variety of similar sulfur-containing thiopheno-benzoquinones. Several archaea such as *A. ambivalens* contain only fragmentary respiratory chains established from NADH- and succinate-quinone reductases and a heme/Cu-type quinol oxidase as terminal electron acceptor; the latter serves as the only energy-conserving proton pump. Rieske Fe-S proteins are present in *Halobacteria*, *Sulfolobales*, and *Pyrobaculum* for example, but cytochrome *c* and regular quinol:cytochrome *c* reductases are absent in many species. Instead, analogous functions are replaced by alternate membrane protein assemblies, for example, the SoxLN complex of *S. acidocaldarius*, using different electron acceptors as, for example, a mono-heme *b*-type cytochrome and/or blue copper proteins like sulfocyanine from various *Sulfolobus* species, or

halocyanines from *Natronomonas* or *Halobacterium salinarum*. The proton pumping terminal heme/Cu-type oxidases are organized as supercomplexes in some thermoacidophilic crenarchaeota that combine features of quinol- and cytochrome *c* oxidases. The best-investigated examples are the SoxM complex and the SoxABCD complex from *Sulfolobus*.

Secondary Energy Transducers

ATP synthetases ($\Rightarrow$) are the most important universal secondary energy transducers integrated into plasma membranes. Bacterial ATP synthetases and those of mitochondria and chloroplasts are of the F_0F_1 -type ($\Rightarrow$). Functionally, the ATP synthetases are reversible ion-transporting ATPases driving the reaction $ADP + P_i \rightarrow ATP + H_2O$ by dissipation of a $\Delta\mu H^+$ or $\Delta\mu Na^+$ across the membrane. F_1 extends to the cytosol and bears the substrate-binding sites; F_0 is the membrane integral ion-conducting subcomplex. Archaea contain A_0A_1 -type ATP synthetases that structurally resemble the eukaryotic vacuolar V-type ATPases ($\Rightarrow$) but, in contrast to the latter, function as ATP synthetases driven by an ion-motive $\Delta\mu H^+$ or $\Delta\mu Na^+$ according to the rotational reaction mechanism of F_0F_1 . The peripheral substrate-binding A_1 moiety has been identified from many *Halobacteria*, *Sulfolobales*, and *Methanobacteria*. The only integrated A_0A_1 -complex was isolated from the methanogen *Methanococcus jannashii*.

Evolutionary Links

In the evolution of higher organisms, cyanobacteria are the most likely precursor of chloroplasts which originated from an endosymbiotic uptake of such a prokaryotic phototroph into a precursor form of a eukaryotic cell. Likewise, the mitochondria have been derived from aerobic prokaryotes similar to the recent purple bacteria by endosymbiosis. The recipient might have been an archaeobacterium.

Glossary

4-HB and 6-HB Highly stable four- and six-helix bundle structures composed of HR domains.

Fusion peptide and fusion loop Hydrophobic attack domains of viral fusion proteins, inserted into target membranes for viral entry.

Fusion pore Resolving of the hemifusion stage through merger of the inner layer, resulting in completion of the fusion process.

Hemifusion Intermediate fusion state in which the outer layers of two approaching lipid bilayers have formed a continuum while the integrity of the inner layers remains uninterrupted.

Heptad repeat (HR) The 4-3 α -helical HR domain, harboring hydrophobic residues in every fourth and third position.

Pseudoatomic structures Overlay of high-resolution X-ray data on electron microscopy-derived electron density maps to reveal the structure of protein complexes *in situ*.

Single-molecule reconstitution Analysis of the activity of individual fusion protein complexes in artificial lipid environments.

Soluble N-ethylmaleimide-sensitive factor association protein receptor (SNARE) A key mediator of vesicular fusion.

Introduction

Membrane fusion is essential for the maintenance of basic functionality of eukaryotic cells and the formation of multicellular organisms. Extracellular fusion, that is, merger of two neighboring cells into a multinucleated syncytium, occurs during embryogenesis and, for instance, during muscle tissue development. Intracellular fusion, that is, merger of internal cellular membranes with each other or the plasma membrane, is, among others, essential for functionality of the eukaryotic secretory system through vesicular transport, activity of the endocytotic system and exocytosis of synaptic vesicles. In a variation of extracellular fusion, lipid-wrapped (enveloped) viral pathogens are required to merge their envelope with cellular membranes for the transfer of their genetic information into a target cell and for the initiation of a new replication cycle.

Despite the fact that every second numerous membrane fusion events take place in a single cell, neither biological nor artificial membranes fuse spontaneously. Rather, efficient membrane fusion depends on the activity of highly specified fusogenic transmembrane proteins. The article commences with an overview of protein mediators of cellular membrane fusion, then proceeds to a discussion of distinct structural classes of fusogenic viral envelope glycoproteins, and concludes with a summary of experimental methods applied to gain structural and mechanistic insight into the membrane-fusion process.

General Principles of Membrane Fusion

The lipid bilayer core represents the energetically most favorable structure of lipids in an aqueous environment. Summarized in the stalk–pore hypothesis ([Figure 1](#)), membrane merger is viewed to proceed through a local bending and

merger of two membranes. A close contact between planar bilayers is disfavored by powerful hydration forces, but highly localized contacts between the tips of protruding dimples appear feasible. Originating at the apex of these dimples, a hemifusion stalk is considered to emerge in which the outer layers of donor and target membrane form a continuum, while the integrity of the inner layers remains intact. Lateral expansion of a stalk results in creation of a hemifusion diaphragm, which is a new bilayer formed by inner monolayers of fusing membranes. Disruption of the hemifusion diaphragm then creates a fusion pore, and subsequent pore enlargement completes the fusion process.

All lipid intermediates described are energetically unfavorable due to the large elastic energy generated upon bilayer bending. In spite of these energetic penalties, membrane merger is effectively induced by cellular and viral fusion proteins. These considerations provide a framework for thinking about the necessary requirements placed on fusion proteins, which include: (1) bringing two membranes into close proximity; (2) promoting bilayer bending and destabilization; and (3) mediating their merger and fusion pore dilation. Additional clues to the mode of action of fusogens are once again provided by lipids themselves. It is well established that lipids with effectively smaller polar headgroup and larger hydrophobic moiety are prone to form curved inverted cylindrical structures and, thus, favor membrane hemifusion that progresses through a stalk intermediate of a similar net curvature ([Figure 1](#)). The membrane-interacting domains of fusion proteins are thought to alter the lipid environment in a way that favors the formation of highly curved nonbilayer intermediates. Recent structural, biochemical, and functional studies revealed that disparate fusion proteins have emerged during evolution. However, they promote membrane fusion through a universal mechanism, perhaps dictated by the common physical properties of lipid bilayers.

Figure 1 Fusion of pure lipid bilayers according to the stalk-pore hypothesis. Key intermediate steps of fusion are the local approach of two bilayers through dimpling, introduction of local high membrane curvature at the apex of protruding dimples, formation of a monolayer stalk, local hemifusion characterized by abutment of distal leaflets, and, finally, creation and enlargement of a fusion pore that completes the fusion process. Lipid headgroups of contacting and distal monolayers are colored blue and red, respectively.

Cellular Fusion Proteins

Although the nature of most *bona fide* mediators of extracellular fusion remains obscure at present, cellular fusogens involved in intracellular and synaptic fusion have been well characterized structurally and mechanistically. We, therefore, take a more detailed view on vesicle budding and fusion to exemplify the intracellular fusion process.

In striking similarity to the principal steps of virion formation and cell entry of enveloped viruses, vesicular transport involves concentration of cargo into the area of a budding vesicle at the donor membrane, scission of the lipid connector between the fully budded vesicle and the donor compartment, specific tethering of the free vesicle to an acceptor membrane, and protein-mediated membrane fusion, releasing the cargo into the acceptor compartment. Unlike the single fusion cycle of viral fusion proteins, however, cellular fusion proteins must be present on both donor and acceptor membrane and undergo an energy-dependent recycling step subsequent to fusion, rendering them capable of mediating multiple fusion events.

To accomplish membrane merger, it is essential that fusion protein rearrangement, which releases energy, is properly coupled to lipid membranes. The fusion process must, thus, be viewed in general as interplay between a complex system of proteins and lipids. Central to the cellular vesicular fusion and recycling machinery is the *N*-ethylmaleimide-sensitive factor (NSF) adenosine triphosphatase, a soluble NSF association protein (SNAP), and, constituting the *bona fide* fusogens, members of the superfamily of transmembrane SNAP receptors (SNAREs). It should be noted that in addition to this core fusion machinery, highly diverse families of tethering factors

are required for fusion activity. Organizing proper vesicular trafficking, these tethering factors form large complexes that, in many cases, directly associate with particular SNAREs and are dedicated to distinct trafficking pathways.

Although SNAREs vary widely in size and structure, they typically feature a short carboxy-terminal luminal tail, a trans-membrane domain (TMD), and a larger cytosolic domain harboring the defining 60–70-amino-acid SNARE motif. Located adjacent to the TMD, the latter includes eight heptad repeat (HR) domains characteristic for α -helical coiled coils. For fusion, SNAREs must be present on both the vesicular (v-SNARE) and the target (t-SNARE) membrane. Binding of a v-SNARE to a cognate t-SNARE complex in either 1:3- or 2:2-stoichiometry then results in the formation of a tetrameric *trans*-SNARE complex, in which the HR domains wrap into a thermodynamically highly stable coiled structure, bringing the v-SNARE and t-SNARE TMDs, and, thus, donor and target membrane into close proximity (Figure 2). Energetically favorable zippering of v- and t-SNAREs into this four-helix bundle structure is considered to be directly coupled to the introduction of local membrane curvature, leading to the formation of a hemifusion stalk. Opening of a fusion pore and, thus, completion of the fusion process coincide with the transition to the *cis*-SNARE complex that unites the TMDs of v- and t-SNAREs in a single lipid bilayer (Figure 2).

Docking of SNAP to the *cis*-SNARE complex and subsequent recruitment of NSF by SNAP initiates SNARE recycling. NSF is considered to catalyze adenosine triphosphate (ATP)-hydrolysis-dependent unwinding of the four-helix bundle, allowing dissociation of the complex and packing of the v-SNARE into a recycling vesicle for transport back to the donor compartment.

Figure 2 Cellular SNARE-mediated vesicle fusion with the plasma membrane. Inset: crystal structure of the fully zippered SNARE four-helix bundle (Protein Data Bank coordinates 3HD7). Top panel shows the vesicle tethering through the initiation of the *trans*-SNARE complex. Close contact and hemifusion are thought to occur through the formation and zippering of the *trans*-SNARE complexes (middle panel). Fusion pores (bottom panel) are likely directly coupled to *cis*-SNARE complex formation.

Viral Fusion Proteins

A unique feature of viral fusion proteins compared to the cell fusion machinery is that the former act in the absence of an external energy source. Here, a key strategy is to generate metastable, kinetically trapped prefusion conformations characterized by a relatively high free energy. An energized conformation of viral glycoproteins is created through a post-translational proteolytic cleavage or through other means. These structures are, thus, ready to refold into a more energetically favorable state while releasing the energy that drives membrane fusion. Both strengths and weakness of viral fusion stem from this principle. On the one hand, the fusion step cannot be usually inhibited by metabolic interventions. On the other hand, the requirements for successful virus entry are quite stringent, so that even under optimal conditions the probability of fusion is usually low. Perhaps as a result of a limited conformational energy, viral fusion is sensitive to the lipid composition of fusing membranes and requires a high density of activated fusion protein oligomers (>1 , probably 5–15 oligomers). The fact that enveloped viruses are devoid of active repair mechanisms has been recently exploited for designing a new class of antivirals that irreversibly diminish the propensity of the viral membrane to fuse, while exerting virtually no adverse effect on the cell membrane that quickly repairs itself.

When triggered by various cues (cellular receptors and/or low pH), viral proteins are thought to undergo the following conformational changes.

First, conserved hydrophobic segments, referred to as fusion peptides or fusion loops, are exposed and inserted into a target membrane (Figures 3–5). This step is critical for coupling the subsequent protein refolding to membrane merger. The insertion of hydrophobic domains also destabilizes the bilayer structure, facilitating the formation of curved lipid intermediates.

Second, viral proteins fold back from an extended conformation, positioning their fusion peptides/loops and TMDs at the same end of an elongated hairpin structure. As the N- and C-terminal ends of viral proteins are anchored to opposing membranes, the hairpins formation is expected to bring membranes together and force their fusion. There is strong evidence that an intermediate referred to as hemifusion (merger of contacting leaflets without the formation of a fusion pore) precedes full fusion. Hemifusion is likely induced by partially refolded protein conformations referred to as prehairpins (Figures 3–5). Progression of fusion through a hemifusion step ensures a nonleaky transition from two bilayers to one continuous membrane, as the inner and outer leaflets are not disrupted at the same time.

Third, in order to release the viral nucleocapsid and initiate infection, nascent fusion pores must enlarge to sizes comparable to the size of a virion. Forces driving the pore enlargement are poorly understood. This step could be driven by recruitment of new fusion proteins into a fusion pore and/or by cellular processes that promote pore dilation.

In summary, structurally diverse unrelated viral proteins appear to undergo a conserved ‘cast-and-fold’ type rearrangement *en route* to fusion. This refolding brings two membranes in contact and promotes their merger by favoring the formation of nonbilayer structures, such as a stalk and a hemifusion diaphragm. These proteins then destabilize the hemifusion diaphragm, likely by pushing the TMDs through the nonbilayer lipid structure. It must be stressed that viral fusion is not a deterministic process. Depending on the experimental conditions, such as the receptor density, pH, and other factors, a varied, but usually small, fraction of virions fuse with a cell membrane. The minimal viral fusion machinery, which relies solely on energy released upon the viral glycoprotein refolding, dictates the need to merge membranes through the least energy-intensive pathway.

Figure 3 Membrane fusion driven by viral class I proteins. Inset: crystal structure of a class I viral fusion protein (paramyxovirus F protein) in pre- and postfusion conformations (Protein Data Bank coordinates 2B9B and 1ZTM). HR domains A and B are colored red and cyan, respectively, in the structure and in the schematic drawing of the F-protein refolding. The model of class I protein-mediated hemifusion and fusion depicts the progression through an extended prehairpin followed by breaking the threefold symmetry and dissociation of the HR-B domains. The final 6-helix-bundle structure is formed by a hairpin arrangement of three monomers with the peripheral positioning of the HR-B domains against the antiparallel central coiled-coil stem formed by HR-A.

Figure 4 Class II viral protein-mediated fusion. Inset: crystal structure of a class II viral fusion protein (Dengue virus E protein) in its prefusion (antiparallel homodimer) and postfusion (homotrimer) conformations (Protein Data Bank coordinates 10AN and 10K8). The color coding of domains I–III is preserved throughout the figure. The schematic of class II protein-induced membrane fusion shows dissociation of prefusion dimers oriented nearly parallel to the viral membrane, engagement of the target membrane through insertion of the fusion loops (yellow) and reorganization into homotrimers. Subsequent refolding of the extended trimeric conformation into a hairpin structure promotes hemifusion and fusion pore formation.

Class I Fusion Proteins

Viral class I fusion proteins are found on major human and also on animal pathogens such as human immunodeficiency virus, influenza virus, Ebola virus, and measles virus, among

many others. Of all fusogenic viral envelope glycoproteins, class I representatives were the first to be described and crystallized in both the pre- and postfusion conformations. Class-defining features are assembly into noncovalently linked homotrimers, synthesis as inactive precursor molecules that

Figure 5 Membrane merger induced by class III viral fusogens. Inset: crystal structure of a rhabdovirus fusion protein (VSV G protein) in its pre- and postfusion conformations (Protein Data Bank coordinates 2J6J and 2CMZ). The coloring of domains I–IV is preserved in the model drawing. The schematic shows that, in reminiscence of the other two classes of viral fusion proteins, also class III proteins engage a target membrane by inserting their fusion loops in an extended intermediate conformation, followed by folding back onto themselves through hairpin formation, thus juxtaposing the fusion loops and the TMDs and forcing membrane merger.

require proteolytic maturation to gain fusion competence, and formation of a thermodynamically highly stable six-helix bundle fusion core structure.

In contrast to host cell fusion complexes, activity of viral fusion proteins is ATP independent. Upon synthesis, class I proteins are rather thought to fold into a metastable, spring-loaded conformation. Proteolysis then liberates the N-terminus of the fusion peptide domain, setting the stage for irreversible refolding into a thermodynamically stable postfusion conformation when a target membrane is in reach. In many cases, the cleavage step is mediated by ubiquitous host furin endoproteases located in the secretory system of the host cell, ensuring that proteolytically matured, fusion-competent complexes reach the cell surface and are incorporated into progeny viral particles. Alternatively, some viruses rely on extracellular proteases for proteolytic maturation subsequent to particle formation. For instance, the haemagglutinin protein of many influenza virus strains is recognized and specifically cleaved by trypsin-like extracellular proteases of the respiratory tract for maturation.

Considering the irreversible nature of class I fusion protein conformational rearrangements, proper timing of the initiation of refolding is essential for productive infection: premature triggering in the absence of a target membrane results in self-inactivation of a viral particle, while delayed fusion activation may miss the narrow window of opportunity available for successful infection. Depending on the viral family, conformational rearrangements can be triggered either at neutral pH through receptor binding (i.e., members of the paramyxovirus family such as measles virus and mumps virus) or through protonation in the acidic environment of the endosome after endocytotic uptake of viral particles (i.e., influenza virus).

Independent of the mechanism of fusion triggering, characteristic for all class I fusion proteins are two HR domains, positioned adjacent to the fusion peptide and TMD, respectively. **Figure 3** illustrates major structural features of the class I fusion process by example of the paramyxovirus fusion (F) protein. In the prefusion conformation, the F protein assumes a lollipop-like structure consisting of a globular head domain that is linked to the TMDs and short luminal tails through the TMD-proximal HR sequences. In this metastable conformation, the fusion peptide-proximal HR domains are broken up into 11 distinct segments forming part of the head structure. Upon fusion activation, major structural rearrangements lead to assembly of the head-domain HR segments into a central, trimeric α -helical coiled-coil structure, propelling the fusion peptides toward the target membrane. Subsequent hairpin-like refolding then positions the individual TMD-proximal HR domains in the grooves of the central triple helix, resulting in the formation of the stable six-helix bundle (6HB) postfusion structure. This final arrangement of a fusion peptide-proximal core coiled-coil structure surrounded by the three TMD-proximal HR helices is a defining feature of class I fusion proteins.

In striking similarity to the coupling of four-helix bundle formation to membrane merger in SNARE complex-mediated vesicular fusion, 6HB formation appears closely linked to the opening of a fusion pore. In both cases, zippering of thermodynamically highly stable α -helical structures is considered to provide the major driving force for pore formation and expansion. Consequently, peptides or small molecules that prevent final 6HB formation of viral class I proteins by interfering with refolding of the fusion protein function as potent viral entry inhibitors and are, as in the case of the HR-derived peptidic HIV entry inhibitor Fuzeon, in clinical use as antiviral therapeutics.

It becomes immediately evident from the schematic shown in **Figure 3** that refolding of the fusion protein trimer cannot proceed symmetrically, as this would wrap the protein into the lipid of the viral envelope. Instead of an umbrella-like folding of the protein through itself, an asymmetric process must, therefore, take place in which individual monomers of the trimer progress through the conformational rearrangements at different rates and individual TMD-proximal HR domains possibly engage the grooves in the central triple helix coiled-coil consecutively rather than in a concerted action.

Class II Fusion Proteins

The envelope glycoproteins of togaviruses and flaviviruses are grouped into class II fusion proteins. Unlike class I viral proteins, these proteins exist as homo- or heterodimers in their native state. With high content of β -sheets, they are structurally distinct from other classes of viral fusogens (**Figure 4**). Homodimer arrangements are typical for the flavivirus E protein exemplified by the tick-borne encephalitis and dengue viruses, whereas E1 proteins of togaviruses (e.g., Semliki Forest virus) are associated with a chaperone protein in their mature form. Furthermore, in contrast to class I proteins, class II proteins are not oriented perpendicular to the viral membrane but run parallel or nearly parallel to the envelope, covering the surface of small icosahedral viral particles.

Class II proteins consist of three major structural domains (DI, DII, and DIII), of which the C-terminal DIII domain is connected to the TMD through a stem region. Another important difference between these and class I fusogens is that, instead of the N-terminal or N-proximal fusion peptides, each class II protein contains an internal fusion loop, which is a part of the DII domain. In the native structure, these loops are sequestered at the dimer interface and are positioned close to the viral membrane.

Although the receptors for class II viruses are generally not identified, these proteins mediate fusion with nearly all cell types by entering through endocytic routes. The ability to fuse at mildly acidic pH extends to fusion with artificial liposomes. The low pH-induced conformational changes proceed through dissociation of homo- or heterodimers and formation of E/E1 homotrimers that engage a target membrane by inserting their fusion loops (**Figure 4**). Subsequent conformational changes involve the reorientation of the DIII domain around a hinge region that positions the transmembrane region and the fusion near each other and presumably within the same membrane. In other words, in spite of the marked differences in their structures, class I and class II proteins appear to progress through a similar refolding pathway: formation of extended conformations followed by the folding into a collapsed hairpin structure, characterized by antiparallel arrangements of the major structural subdomains. As in the final postfusion structure of paramyxovirus F protein discussed above, tight interactions between the inverted DIII domain and the central core stabilize the hairpin structure and thereby promote membrane merger. Functional evidence supporting this notion includes the ability of a recombinant DIII protein to bind to the extended conformation of a class II fusion protein and to block its subsequent refolding and membrane merger.

An interesting feature unique to some class II proteins is that fusion loop insertion into the target membrane and fusion is dependent on the lipid composition. For instance, the low pH-triggered insertion of the Semliki Forest virus E1 into the target membrane is cholesterol dependent, while its ability to fuse membranes is dependent on the presence of small amounts of sphingolipids. In addition, accumulating evidence supports that the late steps of fusion mediated by Dengue virus of the flavivirus family require acidic lipids.

Class III Fusion Proteins

The group of viral class III fusion proteins currently comprises rhabdovirus G protein, herpesvirus gB, and baculovirus gp64. In addition to postfusion conformations of gB and gp64, the structural understanding of this class was greatly advanced by crystallization of the vesicular stomatitis virus (VSV) G-protein trimer in the pre- and postfusion conformations (**Figure 5**). The G protein mediates both receptor binding and, triggered by the low pH of the endosome, membrane merger. Resembling central features of class I and II fusion proteins, refolding from the prefusion conformation assumed at neutral pH involves a prehairpin intermediate that engages both viral envelope and target membranes, and a hairpin-like postfusion conformation in which fusion loop and TMDs rest in close proximity. In striking contrast to the other fusion protein classes, however, G refolding is reversible, adhering to a pH-driven equilibrium. Consequently, the native prefusion conformation is not metastable, enabling the trimer to reassume its native configuration subsequent to transport through the low-pH environment of the Golgi apparatus.

Native G trimers fold into a tripod-like arrangement consisting of four defined sections, a lateral domain with high β -sheet content, a trimerization domain, a PH domain located toward the top of the tripod and, forming the tripod legs, a fusion domain (**Figure 5**). The fusion loops are positioned at the tip of each leg, pointing toward the viral envelope. Of these, the trimerization domain becomes subject to major refolding, while the other domains largely maintain their fold during transition from pre- to postfusion conformation. Among others, exposure to low pH results in protonation of a specific cluster of histidine residues that is located at the intersection between domains and is considered to exude a major destabilizing effect on the prefusion structure. Once triggered, the tripod legs are proposed to swing upward, driving the fusion loops toward the target membrane. Repositioning of the domains with conserved tertiary structure relative to each other through secondary structure reorganization in hinge regions and major changes of the trimerization domain then ultimately result in a classic hairpin postfusion conformation, in which fusion loops and TMDs are positioned in proximity in the same lipid space.

Despite the absence of HR domains in VSV G, two helices of each postfusion domain II engage in formation of an antiparallel 6HB in the postfusion trimer in strong reminiscence of the class I protein fusion core structure. A set of acidic amino acids, brought into close proximity in the central 6HB in the postfusion conformation, appear to serve as a second

major molecular switch to initiate transition back to the native state upon deprotonation at elevated pH.

Methods to Study Membrane Fusion

As discussed above, membrane fusion is a transient and local event. An important confounding factor for mechanistic studies is that fusion occurs in parallel with an excessive number of dead-end protein–lipid interactions that do not lead to fusion. These nonproductive events mask the actual fusion reaction, thereby limiting the use of standard experimental approaches and necessitating the development of new strategies to study cellular and viral fusion.

Fusion Protein Structure

Although membrane proteins in general and viral fusion proteins in particular (by virtue of their metastable nature) are difficult to crystallize, high-resolution structures have been obtained of the ectodomains of a number of SNARE complexes and viral fusion proteins. These are typically based on expression of soluble ectodomain fragments lacking the TMDs. For viral fusion proteins, these ectodomain structures in pre- and postfusion conformations revealed stunning conservation of the refolding pathways. However, less-stable envelope glycoproteins, such as the HIV-1 gp120/gp41, have not been crystallized yet in their native oligomeric form. Recent advances in cryo-electron tomography and image reconstruction techniques bridged the gap between *in situ* light microscopy and crystallography by achieving a resolution of as low as five nanometers for morphologically uniform symmetric viruses. These techniques provide new insights into the architecture of proteins in the viral membrane, their oligomeric status, and lateral distribution. Overlaying cryo-electron tomography-derived electron density maps with available X-ray data allow the generation of pseudoatomic structures that reveal the spatial organization of the native fusion protein complexes at high-resolution *in situ*. Other methods, such as nuclear magnetic resonance, have been successfully applied to solve the structure of smaller protein fragments in solution, including trimeric hairpin subdomains and fusion peptide domains.

Conformational Changes

Major structural changes in fusion proteins have been documented by crystallography, but the available structures are usually limited to native and postfusion conformations of their ectodomains. Less-direct approaches include changes in reactivity to conformation-specific monoclonal antibodies or virus-derived peptides that specifically bind to transiently emerging complementary regions on a refolding fusion protein. Biophysical techniques, such as circular dichroism, calorimetry, and spectroscopy, have been used to study the secondary structure of soluble fragments and changes in the protein structure under fusion-permissive conditions. Exposure of hydrophobic domains (fusion peptides or loops) of viral proteins is often detected based on their association with liposomes or the enhanced fluorescence of dyes binding to hydrophobic domains of these proteins.

Protein–Protein Interactions

Whether or not SNARE-mediated cellular and viral fusions are cooperative processes that require a concerted action of several fusogenic proteins is debated. At least in the case of SNARE-mediated fusion, single-molecule *in vitro* fusion studies support the notion that a lone SNARE complex may in fact be sufficient for fusion. However, efficient, rapidly progressing SNARE-mediated fusion and viral entry require the coordinated activity of multiple fusion complexes. A prevailing view is thus that fusion proteins assemble into multimeric pre-fusion complexes that act cooperatively to promote membrane merger. Importantly, fusion proteins of viruses that rely on auxiliary receptor-binding or regulatory proteins (e.g., herpesviruses and paramyxoviruses such as measles virus and mumps virus) are triggered through lateral interactions with these proteins. Protein–protein interactions and the stoichiometry of pre-fusion complexes have been investigated by biochemical and fluorescence techniques, including co-immunoprecipitation, Foster resonance energy transfer (FRET), and bimolecular complementation. The latter fluorescence techniques report the molecular proximity of two proteins based on either quenching of donor fluorescence by fluorescence acceptor molecules attached to viral proteins or SNARE counterparts (FRET) or assembly of a functional green fluorescent protein (GFP) molecule from its two nonfluorescent subdomains as a result of fusion protein dimerization or oligomerization.

Functional Studies

Functional approaches are widely employed in studies of membrane fusion, permitting detection of lipid merger and monitoring the dynamics of this process. Because membrane fusion involves the establishment of membrane continuity and merger of aqueous compartments delimited by two membranes, fusion is manifested in redistribution of membrane probes and in transfer of aqueous content. Sensitive lipid-mixing assays are also used to detect and characterize a hemifusion intermediate (lipid mixing without content transfer) formed during intracellular, cell–cell and virus–cell fusion. Traditionally, functional studies of viral fusion have relied on the cell–cell fusion model, which provided a convenient means to study the activity of transiently expressed envelope glycoproteins without interference by other viral proteins. This model system is amenable for mechanistic studies employing quantitative fluorescence microscopy, electrophysiology, and flow cytometry assays that detect early steps of fusion on a single-cell level, as manifested by the redistribution of membrane or cytoplasmic fluorescent markers. Somewhat less sensitive, albeit high-throughput-capable, assays rely on protein transfer (enzymes, autofluorescent proteins, or promoters of reporter gene expression) between fusing cells. The end-point measurements of syncytia formation (seen as multinucleated cells) correspond to an ultimate dilation of a fusion pore, which is contingent on a large-scale cytoskeleton rearrangement. Because this assay detects remote consequences of fusion, a lack of syncytia formation may not always indicate absence of function, as small nonenlarging fusion pores can still be present under these conditions.

Single Virion Entry Assays

Direct techniques for monitoring virus–cell fusion (not counting the traditional infectivity assays) have been developed only recently. These assays are based on transfer of virus-incorporated reporter enzymes into the cytosol of a target cell. Advanced fluorescence microscopy techniques permit visualizing entry and fusion of single viral particles. Viral fusion has also been examined using artificial lipid membranes (liposomes and supported bilayers) as targets. Fusion in these minimal model systems allows studies of lipid-dependence and virus–lipid interactions.

In Vitro Reconstitution and Single-Molecule Analysis

Reconstitution of SNARE-mediated fusion of artificial liposomes under *in vitro* conditions has set the stage for the analysis of individual fusion events, a prerequisite for gaining detailed molecular insight into the mechanism of membrane merger as discussed above. Assessment of single molecules in a reconstituted system has been a major breakthrough in our insight into the organization of fusion complexes and the dynamics of the process, because it enables the separation of individual complexes engaged in fusion from the bulk of all molecules in diverse conformational stages that are always present in complex biological systems. Although bulk analysis in the absence of synchronization, thus, returns only the average behavior of the system, the isolated assessment of specific molecules provides a view of the individual molecular fate of a complex engaged in membrane fusion. Frequently coupled with fluorescence methodology, for instance, in single-molecule-FRET studies, protein–protein interactions and protein complex formation can be monitored through this approach while membrane fusion proceeds. These techniques, thus, allow to track the dynamic protein–protein and protein–lipid interactions required for fusion in nearly real time.

Concluding Remarks

The basic principles of viral envelope glycoprotein-mediated membrane fusion, engagement of donor and target membranes followed a juxtaposing membrane-associated domains in the same lipid environment, and local disturbance of the lipid bilayer through introduction of a high degree of membrane curvature have emerged as universally conserved. All viral fusion proteins harbor fusion peptides or loops in addition to the TMDs. Anchoring these in the target membrane in the extended intermediate conformation engages both membranes simultaneously while bypassing the need for a t-SNARE equivalent on the target membrane. By contrast, cellular SNARE proteins must be present in both donor and target membrane, forming a thermodynamically highly stable four-helix bundle that brings the TMDs into proximity. Either four-helix bundle formation or refolding into a hairpin-like structure ultimately brings then the TMDs or TMDs and fusion peptides/loops in close proximity in a continuous lipid environment. This step is directly linked to opening of a fusion pore.

Although X-ray structures of SNARE complexes and viral fusion protein ectodomains in pre- and postfusion

conformations have resulted in a breakthrough in our general structural understanding of membrane fusion, much less is known about the molecular details of lipid merger, the nature of short-lived intermediate conformations of the fusion complexes, and, in the case of viral fusion proteins, their spatial arrangement on the surface of infectious particles. Addressing these questions will likely require interfacing novel-imaging approaches such as cryo-electron tomography reconstructions of emerging fusion pores and refolding complexes with single-molecule analyses of the fusion dynamics in reconstituted systems. Recent advances toward the analysis of SNARE-mediated vesicle fusion have opened a path toward experimentally illuminating the dynamic changes of individual complexes. Application of this approach to viral fusion proteins is anticipated to further boost our understanding of conserved and unique features of the different fusion pathways. Ultimately, detailed, high-resolution structural and mechanistic insight into the viral fusion process has high potential to aid in the development of novel therapeutics through structure-guided drug design.

Membrane Transporters: Na⁺/Ca²⁺ Exchangers

J Lytton, University of Calgary, Calgary, AB, Canada

© 2013 Elsevier Inc. All rights reserved.

Glossary

Alternative splicing A process in which the individual expressed regions of a gene (exons) are arranged in different patterns to produce different messenger RNA (mRNA) molecules that often encode different proteins.

Excitation–contraction coupling The process by which an electrical signal generated in the plasma membrane of a muscle cell results in movement of the muscle fiber proteins and contraction of the cell.

Na⁺/Ca²⁺ exchanger A plasma membrane protein that couples the movement of Na⁺ ions in one direction with Ca²⁺ ions in the other.

Plasma membrane The membrane that surrounds every cell, separating inside from outside.

Retinal rod photoreceptors Long, cylindrically shaped, cells in the retina of the eye that respond to changes in low levels of light.

α-Repeat A short stretch of amino acids identified within the Na⁺/Ca²⁺ exchanger that is conserved among a large superfamily of membrane proteins. Two copies of this conserved sequence are present in each Na⁺/Ca²⁺ exchanger, which are modeled to interact to form the ion-binding and translocation pocket.

Cellular Ca²⁺ Homeostasis

Calcium ion (Ca²⁺) is one of the most ubiquitous intracellular second messengers. Changes in the concentration of Ca²⁺ control a variety of cellular processes including fertilization, proliferation, differentiation, muscle contraction, neuronal signaling, and even programmed cell death. The coordination of such a diverse set of functions is thought to be achieved through Ca²⁺-binding events that are sensitive to complex spatial and temporal patterns of intracellular Ca²⁺ concentration. Unlike other second messenger systems, Ca²⁺ cannot be metabolized, and its concentration is controlled primarily by transport across membranes that bound intracellular compartments (such as the sarco- or endoplasmic reticulum and the mitochondrion) and the cell periphery (the plasma membrane). Cells possess a complex array of different Ca²⁺-transporting mechanisms, and the process of Na⁺/Ca²⁺ exchange is a major contributor to Ca²⁺ efflux across the plasma membrane. The unique and precise nature and arrangement of different Ca²⁺ transport protein molecules in different cells are generally thought to provide a major component of control over complex Ca²⁺ dynamics. When this carefully orchestrated homeostasis goes awry and Ca²⁺ concentrations are dysregulated, the repercussions are usually severe, resulting in damage and cell death which then cause the pathological consequences of diseases such as stroke, neurodegeneration, and heart disease.

Discovery of the Na⁺/Ca²⁺ Exchanger

A competitive relation between the effects of extracellular Na⁺ and Ca²⁺ on intracellular Ca²⁺ and contraction in cardiac, skeletal, and smooth muscle was first noted over 50 years ago. Then, in the late 1960s, three different groups (Reuter, Baker, and DeLuca), working on three different tissue preparations (mammalian cardiac muscle, squid axon, and mammalian

intestinal epithelium) concluded that the coupled counter-transport of Na⁺ for Ca²⁺ across the plasma membrane – so-called Na/Ca exchange – could explain the apparent competitive relation between Na⁺ and Ca²⁺. This finding established the physiological importance of Na⁺/Ca²⁺ exchanger as a mechanism contributing to the control of Ca²⁺ homeostasis, and launched the search for a protein molecule underlying the activity.

The development of biochemical measurements of Na⁺/Ca²⁺ exchanger function in membrane preparations and effective solubilization and reconstitution procedures allowed several groups to partially purify Na⁺/Ca²⁺-exchange activity. Aided by immunological approaches, Philipson's group provided strong evidence that a 120-kDa protein of canine cardiac sarcolemmal membranes, and its 70-kDa proteolytic product, corresponded to the Na⁺/Ca²⁺ exchanger. The use of recombinant expression cloning techniques then led to the seminal molecular cloning work from Philipson's laboratory, published in *Science* in 1990, which confirmed the identity of the canine cardiac Na⁺/Ca²⁺ exchanger.

During the 1980s, studies on visual adaptation in mammalian retinal rod photoreceptors also provided evidence for a Na⁺/Ca²⁺-exchange mechanism responsible for controlling cytosolic Ca²⁺ in that environment. Further biochemical studies of rod Na⁺/Ca²⁺ exchange revealed an obligate dependence on K⁺, and demonstrated that the rod Na⁺/Ca²⁺ exchanger catalyzed the exchange of Na⁺ for both Ca²⁺ and K⁺. As with the cardiac exchanger, solubilization and reconstitution studies allowed purification of the bovine rod photoreceptor Na⁺/Ca²⁺+K⁺ exchanger, which was identified as a ~220-kDa protein. Immunological tools were then used to clone the molecule in 1992 by Cook's laboratory. Surprisingly, despite the mechanistic similarity and a broadly similar topology pattern (Figure 1), the cardiac and rod exchangers share sequence similarity in only two short stretches, which were subsequently termed the 'α-repeats' (see below).

Figure 1 Topology models for $\text{Na}^+/\text{Ca}^{2+}$ exchangers (NCX-type) and $\text{Na}^+/\text{Ca}^{2+}+\text{K}^+$ exchangers (NCKX-type). The predicted folding of each class of protein with respect to the membrane, based on hydropathy analysis and experimental data, is shown. The cylinders labeled M0 (putative signal peptide, removed co- or posttranslationally) to M10 indicate predicted transmembrane helices. The conserved α -repeat regions (α -1 and α -2) are boxed and labeled, as are the two calcium-binding domains of NCX. The location at which Ca^{2+} binds within each domain is illustrated with a gray sphere (four Ca^{2+} bind at this site in domain 1, while two Ca^{2+} bind in domain two). The region subject to alternative splicing is indicated, and shown in gray for NCX and boxed for NCKX. The N-terminus (N) and C-terminus (C) of the mature protein, as well as sites of glycosylation (CHO) are also indicated.

An Expanding Gene Family

Cloning of the canine cardiac $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX1 – gene *SLC8A1*) and the bovine rod photoreceptor $\text{Na}^+/\text{Ca}^{2+}+\text{K}^+$ exchange (NCKX1 – gene *SLC24A1*) opened the exchanger field to molecular analysis. NCX1 was subsequently cloned from heart, brain, and kidney of several different animal species. In the course of these studies, it became evident that the NCX1 gene gives rise to a complex set of alternatively spliced messenger RNA transcripts whose protein products differ in one relatively small region of the protein (Figure 1). The power of molecular cloning was also harnessed to uncover the existence of structurally related gene products, revealing that NCX1 is a member of a gene family that includes two other members, NCX2 (*SLC8A2*) and NCX3 (*SLC8A3*), whose products display about 70% amino acid identity with one another. NCX3 is also subject to alternative splicing, in a similar location as NCX1.

Advances in the molecular analysis of the NCKX family were not so rapid, but by the end of the 1990s a second member, NCKX2 (*SLC24A2*), had been identified. At the turn of the millennium, information contributed to the databases from random-sequencing efforts and from the various animal genome projects had turned the identification of homologous genes

from a bench experiment into a computer search. The discovery of NCKX3 (*SLC24A3*), NCKX4 (*SLC24A4*), and, most recently, NCKX5 (*SLC24A5*) followed rapidly. The NCKX protein family shares lower amino acid similarity than NCX proteins, and is subdivided, with the members of the pairs NCKX1 and 2, and NCKX3 and 4, each sharing about 60% identity, while the identity between pairs is much lower (Figure 2).

During the early phase of homologous gene discovery, it was recognized that NCX1 contains two regions of paired internal similarity, suggesting an ancient gene-duplication event. One pair is found in the cytoplasmic loop of the protein (originally noted as the ‘ β -repeat’) and the other pair resides, one member within each hydrophobic membrane-spanning domain (the ‘ α -repeat’; see Figures 1 and 2). As noted, the α -repeats contain the only regions of similarity between NCX and NCKX exchangers. Moreover, a database search with the α -repeat motif identifies a large number of genes in species ranging from higher vertebrates to flies, worms, plants, yeast, and bacteria (the Ca^{2+} -cation antiporter (CaCA) superfamily). The deduced proteins of these database hits contain two sequences homologous to the α -repeat, each within a relatively hydrophobic region, suggesting that these proteins are all membrane transporters, although, in most cases, the function of the gene products has not been determined experimentally. In some cases, the degree of sequence identity extends beyond the α -repeats, and these genes are likely to be orthologs of known mammalian NCX or NCKX exchanger genes. In other cases, the sequences are quite divergent, and the function of the encoded protein is not clear, but is presumed to involve cation exchange, for example, $\text{Ca}^{2+}/\text{H}^+$ or $\text{Mg}^{2+}/\text{H}^+$ exchange.

Expression of NCX and NCKX in Mammals

NCX1 is ubiquitously expressed in almost all mammalian tissues, with the highest level of expression found in heart, brain, and in kidney. The predominant NCX1 transcript in each of these three tissues corresponds to a different alternatively spliced species. The expression of NCX2 and NCX3 is highly restricted, with NCX2 present at high levels in the brain, but not at significant levels elsewhere, while NCX3 is present in skeletal muscle and at lower levels in selected brain regions, but is not significantly expressed in other tissues. The NCX1 protein has been localized mainly to the T-tubules in cardiomyocytes, to axonal and dendritic processes of neurons, and to the basolateral membrane of distal-convoluted tubule connecting segment cells in the kidney. Studies on localization of the NCX2 and NCX3 proteins are less well developed.

NCKX1, originally defined in rod photoreceptors, is expressed almost exclusively in the eye. NCKX2 is expressed at high abundance in neurons throughout the brain and in the cone photoreceptors, but only at much lower levels elsewhere. Both NCKX3 and NCKX4 are abundant in brain neurons but, in contrast to NCKX1 and NCKX2, are also broadly distributed in a number of other tissues and cell types. NCKX5 is abundant in skin, eye, and selected brain regions. The NCKX1 protein is present in the outer segments of rod photoreceptors. NCKX2 is enriched in neuronal processes particularly in the hippocampus. Little is known about endogenous NCKX3 and NCKX4 protein expression, but when expressed

Figure 2 Phylogenetic relation and sequence alignment. The evolutionary relation between the different murine NC(K)X molecules is shown as a phylogenetic tree based on the combined similarities of the two α -repeat regions. A qualitatively similar pattern is obtained if the entire protein sequence from each isoform is used for the analysis. The sequences corresponding to the two α -repeats are shown aligned. Amino acids that are identical in five or more of the sequences shown boxed, dark shaded and highlighted in bold; chemically similar amino acids are boxed and light shaded.

in recombinant systems, these proteins are clearly found at the plasma membrane like NCKX1 and NCKX2. In distinct contrast, NCKX5 expressed in melanocytes is found on intracellular membranes associated with the *trans*-Golgi complex and melanosome particles. These data define NCKX5 as the only member of the NCX and NCKX families that appears not to reside on the plasma membrane.

Very recently, the only known member of a distinct clade of the CaCA superfamily (the CCX branch), previously characterized as a Na⁺/Ca²⁺ exchanger capable of using Li⁺ to drive Ca²⁺ flux and variously named NCLX or NCKX6 (though not actually a true member of the NCKX branch), was implicated as a component of the long-sought-after mitochondrial Na⁺/Ca²⁺ exchanger. Further analysis and confirmation of this important finding are eagerly awaited.

Structural Properties

Detailed discussion of the structural features of Na⁺/Ca²⁺ exchangers is covered in another chapter in this volume, and

is mentioned here only briefly. Broadly speaking, all the Na⁺/Ca²⁺-exchanger protein family members are predicted to have a similar overall architecture (Figure 1), comprising two hydrophobic membrane-embedded regions separated by a long central cytoplasmic loop. Within each branch of the family (i.e., NCX and NCKX), the length and sequence of each hydrophobic segment are quite well conserved, especially in the α -repeat regions (Figure 2). In contrast to the hydrophobic regions, the sequence of the exposed hydrophilic loops is quite variable between different family members. Of note, although NCKX-family members are predicted to have 10 transmembrane spans and an extracellular C-terminus, NCX1 is predicted to have 9 transmembrane spans and an intracellular C-terminus (Figure 1).

Theoretical models and experimental data indicate that within the transmembrane domains, the two α -repeat regions are oriented in opposite directions (Figure 1). In the case of NCX1, both α -repeats are suggested to form reentrant loop structures that, in the intact protein, come into close physical proximity with one another and form part of the ion-binding and translocation pathway. Studies on NCKX2 have confirmed

a similar structural arrangement, although there is no clear evidence for reentrant loops in either α -repeat in the NCKX proteins.

Recent structural studies on the NCX1 cytoplasmic loop have defined two homologous domains (corresponding to the two β -repeat regions) each comprising an immunoglobulin-like fold with Ca^{2+} bound by the loops at one end of the β -sandwich in a manner reminiscent of C2 domains found in some membrane-associated Ca^{2+} -binding proteins. These two Ca^{2+} -binding domains, together with other regions of the cytoplasmic loop, are responsible for mediating regulation of NCX1 activity (see below). Alternative splicing changes the sequence and properties of the second of the Ca^{2+} -binding domains, resulting in NCX1 proteins with different regulatory properties.

In contrast to NCX1, the large cytoplasmic loop of the NCKX family has not been investigated in any detail. NCKX1, but not the other family members, has an unusually long loop as a consequence of a simple tandem repeat structure. Though this motif is present in NCKX1 molecules from various animal species, the sequence and extent of the repeat are different in each. Several of the NCKX family members are subject to alternative splicing that changes a short region toward the N-terminal end of the cytoplasmic loop. The consequences of these differences on transport function or its regulation are currently not known.

Functional Properties

As their name implies, all $\text{Na}^+/\text{Ca}^{2+}$ exchangers couple the movement of Na^+ ions in one direction to Ca^{2+} ions in the other. An extensive collection of experimental data supports a simple model where the transporter has a single set of ion-binding and transport sites that can be occupied by either Na^+ ions or a Ca^{2+} ion (and in the case of NCKX exchangers, a K^+ ion as well), but cannot be occupied by both Na^+ and Ca^{2+} ions simultaneously. The ion-binding sites on the exchanger must be fully occupied in order for their aqueous accessibility to shift across the membrane barrier (Figure 3). The direction of net ion flux is determined by the relative electrochemical ion gradients across the membrane, and the number of ions that bind to the transporter. The exchanger can, thus, catalyze half cycles of Na^+/Na^+ exchange or $\text{Ca}^{2+}/\text{Ca}^{2+}$ (or in the case of NCKX, $(\text{Ca}^{2+}+\text{K}^+)/(\text{Ca}^{2+}+\text{K}^+)$) exchange, as well as the full cycle of $\text{Na}^+/\text{Ca}^{2+}$ exchange. For NCX1, the ion-binding stoichiometry has been a subject of intense and controversial investigation, but most studies suggest 3 Na^+ :1 Ca^{2+} . For NCKX1 and NCKX2, the stoichiometry has been established as 4 Na^+ :1 Ca^{2+} + 1 K^+ . The stoichiometry of the other NCX and NCKX proteins has not been determined, but is likely to be similar to their paralogous family members.

Although the direction of flux is dictated by thermodynamic considerations, the magnitude of the flux is determined by kinetic and regulatory factors. For NCX1, which has a very high turnover rate, the enzyme is normally limited by the concentration of cytosolic Ca^{2+} , which at rest is well below the concentration for half-maximal occupancy of the transport sites. NCX1 is, thus, activated only after cytosolic $[\text{Ca}^{2+}]$ is elevated by a signaling event. NCX1 activity is also regulated in a complex fashion through various domains of the central

Figure 3 The $\text{Na}^+/\text{Ca}^{2+}$ exchanger reaction cycle. A simple six-state model is shown, where either three Na^+ ions or a single Ca^{2+} ion can bind to the transport site from either side of the membrane in a competitive fashion. Only fully loaded transporter can reorient the aqueous accessibility of the ion-binding sites across the membrane. Note that, in the case of $\text{Na}^+/\text{Ca}^{2+}+\text{K}^+$ exchanger, four Na^+ ions bind instead of three, and K^+ binds and is transported together with Ca^{2+} .

cytosolic loop. Intracellular Ca^{2+} activates the exchanger, while a high concentration of Na^+ causes inactivation. Acidic phospholipids, and adenosine triphosphate through phosphorylation of phosphatidylinositol, also activate the exchanger. Modulation of various kinase pathways has a modest effect on $\text{Na}^+/\text{Ca}^{2+}$ -exchange activity, but there is little convincing evidence for direct phosphorylation of NCX1. In addition, a variety of interaction partners have been proposed to regulate NCX1 activity. Though not studied in nearly as much detail, it appears that the other NCX family members are subject to a similar range of regulatory phenomena.

The rod photoreceptor exchanger, NCKX1, appears to turn-over more slowly than NCX1. On the other hand, NCKX1 has a higher apparent affinity for cytosolic Ca^{2+} and should theoretically be able to drive Ca^{2+} down to very low levels. That this does not happen in rod photoreceptors, suggests that other kinetic or regulatory factors may influence the activity of the molecule. One good candidate for such regulation is the rod-cyclic nucleotide-gated channel, which interacts functionally via Ca^{2+} cycling and also physically associates with NCKX1. Analysis of NCKX function in brain neurons confirms expectations from recombinant systems and reveals a high-capacity transport system that contributes to Ca^{2+} homeostasis when intracellular $[\text{Ca}^{2+}]$ levels are elevated above baseline levels. Recent studies have suggested that, analogous to NCX1, NCKX2 is subject to a Na^+ -dependent inactivation process involving occupancy of cytoplasmically disposed Na^+ -transport sites. NCKX2, but not NCKX3 or NCKX4, is stimulated by protein kinase-C in a complex manner that appears to involve phosphorylation of three serine/threonine residues residing in separate cytoplasmic locations. The mechanism that leads from phosphorylation to activation of transport in NCKX2 has not yet been delineated.

Physiological Relevance

In the heart, it is clearly established that NCX1 plays a critical role in relaxation by lowering Ca²⁺ during diastole. Additionally, during the early phase of the cardiac action potential, as the membrane depolarizes and ion gradients change, NCX1 probably contributes to Ca²⁺ entry and excitation–contraction coupling. Furthermore, as NCX1 switches to Ca²⁺ extrusion later in systole, it creates a depolarizing current that can significantly modulate the shape of the action potential. Normally, these contributions of NCX1 to cardiac excitation–contraction coupling are integrated into overall Ca²⁺ homeostasis. However, during pathological circumstance, the expression pattern of Ca²⁺ channels and transporters changes, and ion concentrations and gradients are altered dramatically. Under these conditions, changes in NCX1 activity may be maladaptive, and so may contribute to, rather than protect against, deleterious consequences. Recent studies using mice harboring a cardiac-specific knockout of NCX1 have shed light on several of these intriguing issues.

In the kidney, very high levels of NCX1 are found on the basolateral aspect of a selected population of distal nephron cells. In this environment, NCX1 contributes to the control of extracellular, systemic, Ca²⁺ homeostasis by driving the active transcellular reabsorption of Ca²⁺. NCX1 is also present in brain neurons and astrocytes, where it presumably plays a role in Ca²⁺ extrusion under resting conditions, but may participate in Ca²⁺ entry under certain circumstances. Recent evidence has suggested that expression of NCX1 in vascular smooth muscle cells plays a central role in regulating vessel tone and may contribute to susceptibility to salt-sensitive hypertension.

The unique and specialized role that NCX1 plays in controlling Ca²⁺ flux and homeostasis in heart and kidney is also reflected in the fact that this gene is expressed under the control of three different, and tissue-specific, promoters. One promoter is used essentially exclusively in heart, one exclusively in kidney, while the third is used widely in various other tissues. This arrangement provides the opportunity for expression of the heart and kidney NCX1 molecules to be regulated independently and to be responsive to the specialized Ca²⁺ homeostasis requirements of these tissues.

The distinct contributions provided by the NCX2 and NCX3 proteins have recently been investigated using gene-targeted knockout models. NCX2 was demonstrated to have an important stabilizing contribution to Ca²⁺ homeostasis in neuronal processes at both pre- and postsynaptic sites. Inactivation of NCX2 resulted in increased hippocampal plasticity and enhancements of memory and learning. NCX3 knockout animals, by contrast, displayed defects in neuromuscular transmission and increased muscle necrosis compared to wild-type counterparts.

In the rod photoreceptors, NCKX1 is thought to play a critical role in maintaining Ca²⁺ homeostasis, especially in

the dark when cyclic-nucleotide-gated channels are open and so the membrane is depolarized, the Na⁺ gradient is low, and Ca²⁺ flux is high. Under these circumstances, the thermodynamic power derived from the 4 Na⁺:1 Ca²⁺ + K⁺ coupling ratio is necessary to allow continued Ca²⁺ efflux. It would seem reasonably likely that similar requirements for continued Ca²⁺ efflux in the face of depleted ion gradients, reduced membrane potential, and elevated cytoplasmic [Ca²⁺] – for example, during high-frequency action potential firing in a neuron – underlie the expression of NCKX isoforms at various cellular and tissue sites. The specific roles for the different NCKX isoforms are now beginning to be resolved through analysis of mice models with specific gene-targeted knockouts. Recent data demonstrate that NCKX2 has a nonredundant role in supporting normal hippocampal synaptic plasticity underlying a set of experience-dependent motor learning and memory behaviors.

In a recent exciting discovery, NCKX5 was demonstrated to be essential for normal pigmentation in zebrafish. Importantly, a nonsynonymous single-nucleotide polymorphism within a conserved part of the NCKX5 protein-coding region is associated with a major quantitative contribution to skin pigmentation in human populations. The resulting nonconservative substitution of Thr for Ala at position 111 is associated with lighter skin color in people of Northern-European ancestry. Intriguingly, NCKX5 function has not yet been measured, and how the A111T polymorphism leads to changes in pigmentation still remains to be elucidated.

The distinct individual physiological roles, as well as the underlying molecular mechanisms, for the expanding family of NCX and NCKX protein molecules continues to be an active area of research that is likely to provide exciting novel insights into Ca²⁺ homeostasis and its dysregulation in disease.

Glossary

Active transport Transport of a solute against a chemical (concentration) and/or electrical potential difference that is directly (primary) or indirectly (secondary) driven by metabolic energy.

Carrier Integral proteins that span the membrane phospholipid bilayer and are capable of binding a solute(s) and catalyzing translocation from one side of the membrane to the other.

Channel Integral proteins that span the membrane phospholipid bilayer and provide water-filled passageways (pores) for the diffusion of solutes.

Diffusion Flow of a solute from a region of higher to a region of lower chemical (concentration) and/or electrical potential driven solely by thermal random motion of solute particles.

Facilitated diffusion Carrier-mediated transport processes that are not coupled to a supply of metabolic energy and, thus, can only result in the equilibration of a transport solute across the membrane.

The term 'membrane transport' refers to processes that bring about the movement of solutes and water across the barrier, or envelope that surrounds all living cells in the animal and plant kingdoms. These processes are responsible for two ubiquitous characteristics of living cells, namely: (1) the ability to maintain constant, or near constant, intracellular compositions that differ from the extracellular environment, containing the highly specialized molecules essential for metabolism and replication and, at the same time, (2) the ability to selectively exchange matter and energy with that environment.

All cell membranes consist of a double layer of phospholipids oriented so that their electrically charged, hydrophilic (or water-loving) head projects into the interior and exterior of the cells, respectively, and their lipid tails, which are hydrophobic (or water-fearing), project inward and form an oily core. Floating in this oily structure are surface or peripheral proteins that do not extend through the thickness of the bilayer, and integral proteins that span the bilayer and provide pathways for direct communication between the intracellular and extracellular compartments. This lipoprotein bilayer model, which consists of large expanses of lipid studded here and there with protein, is illustrated in [Figure 1](#).

Exchange of solutes and water across the lipoprotein barrier takes place through the lipid as well as through integral proteins and can be classified as (1) simple diffusion; (2) diffusion through pores or channels; and (3) carrier-mediated transport. The latter may be subdivided into facilitated diffusion (or facilitated transport), primary active transport, and secondary active transport.

Simple Diffusion

The simplest form of membrane transport was recognized more than a century ago by Overton, who noted that the ease with which a large variety of molecules cross plant cell membranes is proportional to their solubility in lipids; indeed, it is the observation that first suggested that the membranes

were composed of lipids. In essence, he suggests that the molecule simply dissolves in the lipid across one surface, passes through this oily barrier, and exits at the other side. The rate of this process is given by a modification of a law derived by Fick in 1855:

$$J_i = k_i D_i \Delta C_i$$

where J_i is the rate of diffusion of solute i across the membrane (in amount of solute per unit time), k_i a measure of the solubility of the solute i in oil compared to water (oil:water partition coefficient), D_i the diffusion coefficient of i or the mobility of i in the lipid, and ΔC_i the concentration difference of i across the membrane. The product $k_i D_i$ is often abbreviated as the permeability coefficient P_i .

Overton demonstrated that a linear relation between J_i and k_i in plant cells and this relation, now referred to as Overton's law, has been confirmed repeatedly.

Diffusion through Pores or Channels (Restricted Diffusion)

Lipid membranes are essentially impermeable to ions and are only slightly permeable to water. It is now clear that these highly hydrophilic molecules traverse cell membranes through integral proteins that form water-filled pores or channels that span the bilayer. Although the presence of holes in membranes had been speculated as early as the 1850s and were strongly suggested by the pioneering work of Hodgkin, Huxley, and Keynes on the squid axon in the 1950s, they were established beyond doubt, more recently, by Hille, Armstrong, and MacKinnon.

Although some use the terms pore and channel interchangeably, others prefer to employ the word pore for integral proteins that are continually open to the two aqueous compartments on both sides of the membrane (using the analogy of an open pipe) and reserve the word channel for a pore that has a gate that determines how long it will be in the fully open

Figure 1 Illustration of phospholipid bilayer with peripheral proteins adhering to the surfaces and integral proteins spanning the thickness of the membrane. One integral protein is portrayed as a channel. The charged head groups of the phospholipids are represented as circles and the lipophilic fatty tail groups as the wavy lines forming the core of the bilayer.

state and how long it will be closed (the analogy being a pipe with shutter).

In general, then, channels have gates that determine the probability that they will be in the open state at any time (open-time probability) and how long they will stay open (mean open time). The properties of these gates may be influenced by the electrical potential difference across the membrane (voltage-gated channels), the binding of one or more ligands (ligand-gated channels) or both. In addition, they possess 'filters' that confer selectivity on the channel; the structural characteristics of ion channels that result in a high preference for one ion over the other have recently been unraveled for potassium channels.

Movement of an ion through an open channel obeys a form of Ohm's law for current flow caused by a conductance driven by an electrochemical potential difference. Thus,

$$i_i = g_i(V_m - E_i)$$

where i_i is the rate of flow of the ion through a single open channel given in electrical terms of amperes (this is analogous to J_i) and g_i the conductance of the channel (analogous to P_i). V_m is the electrical potential difference across the membrane and E_i the Nernst equilibrium potential for the ion so that the difference ($V_m - E_i$) is the displacement of the ion from equilibrium in electrical terms, and is thus the driving force for flow. More than one million ions may traverse a single channel per second so that single channel currents may be readily recorded using a variety of techniques. The ionic current through an ensemble of such channels is $I_i = i_i N_i p_o$, where N_i is the total number of channels and p_o the open probability.

Carrier-Mediated Transport

Carrier-mediated transport differs from diffusion through lipid phase, pores, or channels in that after entering the integral protein the transported solute(s) bind to a specific site(s) on this protein which then undergoes some translocation that exposes and/or releases them to the other side. Unlike pores or channels, carriers are not open to both sides of the

membrane simultaneously. Because conformational changes are necessary for carriers to function, the number of molecules transported per second is orders of magnitude less than pores. In this sense, carriers may be viewed as enzymes that do not chemically alter the transported species (substrate) but, instead, catalyze a change in their location. For this reason, the terms permeases and translocases are used in some instances as synonymous with carriers. Indeed, one characteristic of carrier-mediated transport is that it displays Michaelis–Menten saturation kinetics, marked by a maximum transport velocity (J_m) and a solute concentration needed to achieve a half-maximal transport velocity (K_t), and often obeys the simple relation:

$$J_s = \{[S]J_m/K_m + [S]\}$$

where J_s is the rate of transport and $[S]$ the concentration of the transported solute. (Note: this relation describes the initial rate of transport when there is solute present on one side of the membrane only.)

Facilitated Diffusion

The earliest recognized and simplest form of carrier-mediated transport is facilitated diffusion, often called facilitated transport, in which an otherwise impermeant solute binds to a site on an integral protein (carrier) from one side of the membrane and then undergoes a translocation that provides the solute access to the other side. The classic example of facilitated diffusion is glucose transport across the membranes of cells such as erythrocytes, muscle, and adipocytes. The carriers that mediate this transport have been cloned and sequenced and fall into a group of proteins that have 12 membrane-spanning segments called glucose transporter (GLUT). Urea is transported across the membranes of many cells by a facilitated transporter called UT.

It must be emphasized that because these carriers are not directly or indirectly coupled to a supply of energy, they cannot perform osmotic work, that is, they cannot transport a neutral solute against a concentration difference (e.g., from lower to higher concentration) or a charged solute against a combined electrochemical potential difference. Thus, like diffusion, facilitated diffusion carriers bring about equilibration; transport ceases when intrinsic thermodynamic driving forces are abolished.

Active Transport

Active transport is the term reserved for transport processes that result in the movement of a solute uphill or against its natural direction. For the case of a neutral solute (at constant temperature and pressure), this resolves into movement against a concentration difference; for a charged solute, it is movement against the combination of concentration and electrical potential differences. This is work (e.g., charging a battery) and it therefore requires the investment of energy.

There are two groups of carrier-mediated active transport processes: those where the coupling to energy is direct and those where the coupling to energy is indirect.

Primary Active Transport

Primary active transport processes are capable of coupling energy directly to the uphill movement of the transported species. By far the most abundant, and well-understood, primary active transporters are the retinylidene proteins or, more commonly called, rhodopsins, capable of coupling light energy to ion transport. Bacteriorhodopsins found in *Archaea*, *Cirrhacea*, and some eukaryotic and prokaryotic cells pump protons out of these cells, thereby establishing a 'proton-motive force' across the membrane. Halophilic bacteria possess a form referred to as halorhodopsin that pumps Cl^- into cells. These transporters have been studied extensively using high-resolution crystallography and all possess seven membrane-spanning segments attached to a chromophore.

In higher animals, all primary active transporters are ATPases, that derive the energy for moving the transported solute against a thermodynamic driving force (i.e., uphill) from adenosine triphosphate (ATP) hydrolysis. The most prevalent is the Na-K pump found in virtually all cells from higher animals and responsible for pumping three Na^+ ions out of the cell and two K^+ ions into the cell for every ATP hydrolyzed. This pump is responsible for the fact that these cells have a lower intracellular Na^+ concentration and higher intracellular K^+ concentration than the concentrations of these ions in the surrounding extracellular fluid. As is discussed below, the extrusion of Na^+ from the cell establishes a 'natrio-motive' force across the membrane analogous to the proton-motive force established by light-driven proton pumps in lower life forms. The detailed mechanism of action of the Na-K pump is not well established except for the fact that it is a member of a superfamily of ATPases referred to as $\text{E}_1\text{-E}_2$ ATPases or P-type ATPases, because the operation of the pump involves cycling between two configurations of the protein driven by phosphorylation and dephosphorylation reactions.

Other ATPases that perform primary active transport include the Ca^{2+} ATPase found in muscle and responsible for regulation of the Ca^{2+} activity of the cytoplasm, the $\text{H}^+\text{-K}^+$ ATPase of gastric parietal cells responsible for secreting protons into the gastric juice in response to appropriate stimuli, and the H^+ ATPase that is responsible for acidifying intracellular organelles such as lysosomes and endosomes.

Secondary Active Transport

Secondary active transport processes bring about the uphill transport of one or more solutes but do not derive the necessary energy from direct coupling to a source of metabolic energy. Instead, these transport processes are energized by coupling those movements to the downhill movement of another solute.

Co-Transport (Symport)

The uphill or secondary active transport of a large number of solutes into cells of higher animals is coupled to the downhill

movement of Na^+ . Thus, the carrier protein binds both the transported solute and Na^+ from the extracellular solution. Inasmuch as the Na^+ concentration in the intracellular solution is lower than that in the extracellular solution, because of the action of the $\text{Na}^+\text{-K}^+$ pump as discussed, this coupling permits the downhill movement of Na^+ and provides the energy for the uphill movement of the coupled solute. In essence, the energy invested into the $\text{Na}^+\text{-K}^+$ pump by the hydrolysis of ATP has set up a Na^+ -gradient or natrio-motive force across the membrane that can be deployed to energize the secondary active transport of solutes whose translocation across the membrane is coupled to that of Na^+ .

In many lower forms of life, secondary active co-transport is energized by the H^+ gradient or proton-motive force across the membrane established and maintained by light-driven primary active extrusion of protons, as discussed above.

Counter-Transport (Antiport)

Coupling to the downhill movement of Na^+ into cells can also serve to energize the uphill or secondary active transport of solutes out of cells. Important examples of counter-transporters are the $\text{Na}^+\text{-H}^+$ exchanger responsible for extruding H^+ from cells and the regulation of cell pH and the $\text{Na}^+\text{-Ca}^{2+}$ exchanger responsible for extruding Ca^{2+} from many cells.

Na^+ -coupled co- and counter-transport processes are very diverse and are beautiful examples of bioenergetic economy where a single primary active transport process directly coupled to the hydrolysis of ATP can establish a transmembrane ion (Na^+) gradient that can, in turn, be utilized to energize a wide variety of secondary active transport processes.

Messenger RNA Degradation in Bacteria

D H Bechhofer, Mount Sinai School of Medicine, New York, NY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Endonuclease Enzyme that cleaves an internal phosphodiester bond.

Exonuclease Enzyme that cleaves a terminal phosphodiester bond, at a 5' end or a 3' end.

Oligoribonuclease Enzyme that degrades short oligonucleotides to mononucleotides.

Phosphorolysis Cleavage of a nucleotide bond by addition of inorganic phosphate, rather than the more common hydrolysis, which adds water.

Poly(A) polymerase Template-independent enzyme that adds A nucleotides at an RNA 3' end.

Transcription termination The process by which RNA polymerase is removed from its DNA template and RNA synthesis ceases.

Transfer messenger RNA (tmRNA) The RNA that binds to a stalled ribosome and transfers it to its own coding sequence for renewed translation. The peptide that is generated is marked at its C-terminal end for degradation by proteases.

General Aspects of Bacterial Messenger RNA Decay

Regulation of gene expression occurs at many levels, including the fate of a messenger RNA (mRNA) after its synthesis. In eukaryotes, regulation of gene expression at this posttranscriptional level includes all activities that affect the ability of an initial transcription product to function in translation, such as capping, splicing, polyadenylation, export to the cytoplasm, and degradation. In prokaryotes, self-splicing occurs rarely, transcription and translation are not separated by a membrane barrier, and polyadenylation occurs but to a much lesser extent. The study of posttranscriptional gene regulation in prokaryotes is therefore concerned mainly with mRNA degradation.

Bacterial mRNA half-lives are measured by adding an inhibitor of bacterial RNA polymerase, most often rifampin, and following the decline in the level of a specific mRNA over time by Northern blot analysis or reverse transcription-polymerase chain reaction, or following decay of mRNA globally in a microarray experiment. The half-lives of bacterial mRNAs are generally only a few minutes, unlike the much longer-lived eukaryotic mRNA. Rapid turnover of bacterial mRNA is likely an important factor in the ability of bacteria to respond to changes in their environment and nutritional sources. Thus, the degradation of an mRNA will free up ribosomes to translate newly synthesized mRNAs that are induced by such changes. In addition, mRNA degradation releases free nucleotides to the pool from which new nucleoside triphosphates are made and then used in RNA synthesis. As such, decay of mRNA is an essential process, required for life. Nevertheless, the range of bacterial mRNA half-lives varies from <1 min to >30 min. The half-life of a particular mRNA will be a function of susceptibility to ribonuclease attack, which is determined by its specific sequence/structure and its interaction with elements of the translational apparatus and other proteins or small RNAs.

The process of mRNA decay is divided into two stages: (1) rate-determining initiation of decay and (2) complete turnover of the mRNA to nucleotides. The most efficient way to remove an mRNA from the set of translated messages would be to make the mRNA unrecognizable to ribosomes by degrading the sequence that constitutes the 5'-proximal

ribosome-binding site (RBS). This could be accomplished by exoribonucleolytic decay from the 5' end. However, a 5'-to-3' exoribonuclease is not known to exist in *Escherichia coli*, and, until very recently, it was thought that the absence of such an enzyme in *E. coli* meant that bacteria generally do not contain a 5' exoribonuclease. In eukaryotes, by contrast, decapping enzymes and 5' exoribonucleases are widespread. Because of the absence of a 5'-to-3' exonuclease, the hypothesis developed that initiation of bacterial mRNA decay occurs by an internal endonucleolytic cleavage, followed by rapid decay of the upstream and downstream products of such cleavage. This mechanism is reflected by the fact that Northern blot analysis of an mRNA in a wild-type bacterial strain will usually detect only the full-length mRNA and no decay intermediates. Strains that are deficient in one or more ribonucleases are required to detect intermediates in the decay process.

Surprisingly, over a decade after complete genome sequences of well-studied organisms began appearing, new enzymes that participate in mRNA decay are still being discovered. We focus on the ribonucleases of two representative eubacteria: *E. coli*, the model Gram-negative organism, and *Bacillus subtilis*, the model Gram-positive organism. The overwhelming majority of studies on bacterial mRNA decay have been done in these two organisms, and the complement of ribonucleases (Table 1) and the mechanism of mRNA decay differ significantly between them.

Ribonucleases Activities

RNase E

The essential endoribonuclease of *E. coli* is named RNase E. RNase E-related enzymes are present in many bacterial species and are thought to be the primary decay-initiating enzyme in these organisms. RNase E is a 5'-end-dependent endonuclease, that is, it binds to the 5' end of an mRNA and then locates a target site at which it cleaves endonucleolytically. The activity of RNase E is at least an order of magnitude more active on an mRNA with a 5'-monophosphate end than the 5'-triphosphate end that is present in the initial transcript. This feature ensures that an mRNA is not attacked immediately as RNA polymerase

Table 1 Ribonucleases involved in mRNA decay in *E. coli* and *B. subtilis*

Ribonuclease	Gene name	Cleavage specificity	<i>E. coli</i>	<i>B. subtilis</i>	Characteristics
RNase E	<i>rne</i>	Endonuclease	Yes	No	5'-End-dependent, inhibited by 5' triphosphate end
RNase G	<i>rng</i>	Endonuclease	Yes	No	Some functional overlap with RNase E
RNase II	<i>rnb</i>	3' Exonuclease	Yes	No	Major turnover enzyme in <i>E. coli</i>
RNase III	<i>rnc</i>	Endonuclease	Yes	Yes	Recognizes double-stranded structure
RNase J1	<i>rnjA</i>	Endonuclease 5' Exonuclease	No	Yes	Endonuclease activity insensitive to 5' phosphorylation state; exonuclease activity requires 5' monophosphate end
RNase J2	<i>rnjB</i>	Endonuclease	No	Yes	Forms a complex with RNase J1; poor 5' exonuclease activity
RNase R	<i>rnr</i>	3' Exonuclease	Yes	Yes	Degrades through secondary structure
RNase Y	<i>rny</i>	Endonuclease	No	Yes	Prefers 5'-monophosphate end
PNPase	<i>pnp</i>	3' Exonuclease	Yes	Yes	Phosphorolytic; major turnover enzyme in <i>B. subtilis</i>

begins synthesizing it. Indeed, recent studies have shown that an early step in the decay of a number of *E. coli* mRNAs is the conversion of the 5'-triphosphate nucleoside to a 5'-monophosphate nucleoside by the action of a phosphohydrolase enzyme. Thus, accessibility of the 5' end is a major determinant of mRNA half-life. For example, the formation of strong secondary structure at the 5' end by base-pairing of 5'-proximal nucleotides will stabilize diverse downstream sequences. The internal target site for RNase E cleavage is in a single-stranded segment that is AU rich, often located near a region of RNA secondary structure. How a 5'-binding enzyme finds its internal target site is a matter of intense speculation. The mechanism could involve looping out of uncleaved mRNA and positioning of the target sequence in the enzyme catalytic site. As RNase E is thought to exist mostly as a tetramer, 5'-end binding could coordinate structural changes of monomers in the complex to position the target site appropriately. In some cases, RNase E can locate and cleave at an internal target site independent of binding at the 5' end (direct access).

Starting mRNA decay process by RNase E cleavage could be a dangerous strategy, if the resulting upstream fragment was not degraded rapidly. A ribosome could still bind and initiate translation of this fragment, leading not only to synthesis of a nonfunctional peptide but also to a ribosome stuck at the 3' end of the fragment with no stop codon to signal its release. Although bacteria do have the specialized transfer messenger RNA (tmRNA) system (see below) that allows off-loading of ribosomes from nonstop mRNA fragments (i.e., mRNA fragments that contain an RBS and an open reading frame but no stop codon), the capacity of this system is limited. In fact, the products of RNase E cleavage do not persist due to the nature of their ends (Figure 1(a)). The upstream fragment that is generated by RNase E has a 3'-hydroxyl end, and is rapidly degraded by the action of 3' exonucleases: RNase II, polynucleotide phosphorylase (PNPase), and RNase R (Table 1). There are several other *E. coli* 3' exonucleases, but they are involved in processing of stable RNAs. Thus, as soon as RNase E makes an endonucleolytic cut, the upstream fragment bearing the RBS is on its way to being converted to mononucleotides. The downstream mRNA fragment generated by RNase E cleavage bears a 5'-monophosphate end, and this is an excellent substrate for further RNase E binding and cleavage. Accordingly, the initial cleavage by RNase E is the trigger for a rapid process that leaves no long-lasting intermediates (Figure 1(a)).

Degradosome

An interesting aspect of RNase E is that it nucleates a protein complex known as the RNA degradosome. The N-terminal half of the RNase E protein, which is strongly conserved in other species, contains the catalytic domain. Many bacteria also contain a smaller ribonuclease known as RNase G, which resembles the N-terminal half of RNase E and has similar endonucleolytic activity. The fact that RNase E is essential suggests that RNase G cannot substitute for it *in vivo*. The C-terminal half of RNase E is less well conserved and contains an arginine-rich RNA-binding domain, as well as several protein sites that are docked by three other proteins: (1) RhlB, an RNA helicase that unwinds double-stranded RNA; (2) the aforementioned 3'-exonuclease PNPase; and (3) enolase, an enzyme involved in glycolysis. The C-terminal region of RNase E thus serves as a scaffold for the protein complex that constitutes the degradosome. Clearly, RNase E, RhlB, and PNPase could function in concert to accomplish mRNA decay, with RNase E making an initial cut, PNPase degrading the upstream fragment in the 3'-to-5' direction, and RhlB unwinding helices ahead of PNPase (see below). The presence of a degradosome complex, however, is not essential, as *E. coli* cells that carry only the N-terminal half of RNase E are viable. The existence of a degradosome complex has been established for a number of bacterial species, but remains controversial in others, including *B. subtilis*.

3'-to-5' Exoribonucleases

We mentioned the activity of 3'-to-5' exoribonucleases in degrading the upstream product of endonucleolytic initiation of decay. Most bacterial species contain more than one 3'-to-5' exonuclease that degrades mRNA fragments. In *E. coli*, the major exoribonucleases that perform this function are RNase II and PNPase, and a strain that is missing both of these activities is inviable. While RNase II and most exoribonucleases are hydrolytic enzymes, which add water across a phosphodiester bond, PNPase is unusual in that it is a phosphate-dependent enzyme that carries out phosphorolysis, which releases a nucleoside 5' diphosphate (Figure 2). It has been argued that bacteria that live in energy-poor environments may rely more heavily on PNPase activity for RNA decay, as this preserves the phosphate bond energy in the decay products. Interestingly, *B. subtilis*, which lives in energy-poor

Figure 1 Models for mRNA decay in (a) *E. coli* and (b) *B. subtilis*. Alternative pathways are shown for *B. subtilis*. Shaded 3'-to-5' exonucleases in (a) represent RNase II or PNPase. The major 3'-to-5' exonuclease in (b) is PNPase (indicated by the P). Orn, oligoribonuclease; NMPs, nucleoside monophosphates; NDPs, nucleoside diphosphates.

soil (unlike *E. coli*, which lives in the energy-rich gut), contains PNPase but not RNase R. Another 3'-to-5' exonuclease that has been shown to be involved in mRNA decay is RNase R, which is unusual in being able to degrade through strong secondary structure, provided it is given a long-enough single-stranded tail for binding (optimally 10 nucleotides). According to recent models, the choice of which 3' exonuclease will degrade the mRNA fragments generated by endonuclease cleavage will depend on the intrinsic RNA structure. Unstructured RNAs will be substrates for any of the three enzymes. Structured RNAs will be substrates for PNPase in conjunction with RhlB, or for RNase R.

Because most bacteria contain multiple 3' exoribonucleases, the effect of knocking out a gene encoding a particular 3' exoribonuclease may be difficult to detect, and multiply mutant strains are often required to see the effects of a missing ribonuclease. Such is not the case for *B. subtilis*, in which PNPase is the dominant ribonuclease activity of its four known 3' exoribonucleases. This is seen in experiments that measure the steady-state level of decay intermediates in wild-type versus ribonuclease mutant strains (an example is shown in Figure 3). In strains that contain all four of the known 3' exonucleases or only PNPase, only the full-length RNA is

detected. In strains that do not contain PNPase, decay intermediates are detected (although much less so in the strain containing RNase R alone) at levels that exceed the amount of full-length RNA.

Despite the presence of multiple 3' exonucleases, initiation of decay from the native 3' end of mRNAs contributes little to the overall decay mechanism. This is because of the nature of the 3' end of mRNAs that are terminated in a factor-independent manner. Factor-independent termination of transcription relies on the formation of a structure by complementary GC-rich RNA sequences, which is followed by several U residues. Synthesis of such a sequence causes RNA polymerase to fall off the DNA template, leaving an RNA with a strong secondary structure very near the 3' end and only a short single-stranded tail. Such structures are intrinsically resistant to degradation by 3'-to-5' exoribonucleases, such as RNase II and PNPase, and the 3' single-stranded tail is too short for RNase R binding. There is another mechanism of transcription termination that relies on the RNA-binding protein Rho, which leaves unstructured 3' ends. However, termination that is not Rho dependent is much more prevalent, and most studies of bacterial mRNA decay deal with mRNAs that are terminated in a factor-independent manner.

Figure 2 Phosphorolysis vs. hydrolysis. The boxed structure is the 3' end of an RNA chain of n residues, ending in guanosine and adenosine residues. The end nucleotide can be cleaved by the addition of inorganic phosphate (top) or water (bottom), generating a chain of $n-1$ residues and a nucleoside diphosphate (top) or a nucleoside monophosphate (bottom).

Figure 3 Northern blot analysis of accumulation of mRNA decay intermediates in *B. subtilis* ribonuclease mutants. Migration of the full-length (FL) mRNA is indicated by the arrow at right. Decay intermediates are observed neither in the wild-type strain (lane 1) nor in the strain containing only PNPase (lane 3). Marker lane (M) contains labeled DNA fragments of the indicated sizes.

PAP-mediated decay of 3'-end-containing fragments

The mechanism of *E. coli* mRNA decay described so far does not have a way of dealing with mRNA fragments that contain the 3'-terminal transcription termination structure, which would not be substrates for the single-strand-specific activity of RNase E. Rather, these fragments are degraded from their 3' end with the assistance of poly(A) polymerase (PAP), a DNA-independent RNA polymerase that adds A residues to a 3' end. Extension of the 3' end by poly(A) addition provides a toehold for 3' exonucleases to bind and begin degradation in the 3'-to-5' direction (Figure 1(a)). When the exonuclease proceeds a short distance but is blocked by secondary structure and falls off, PAP again adds a poly(A) extension and gives a 3' exonuclease another crack at degrading from the 3' end. This process occurs iteratively, until the 3'-proximal structure can no longer form, and the fragment is degraded.

RNase J Family

When completed bacterial genome sequences began accumulating in the late 1990s, it soon became clear that many species, including *B. subtilis*, had no sequence homolog of RNase E/G. Nevertheless, many studies showed that initiation of mRNA decay in these organisms was also 5'-end dependent. Uncertainty about decay initiation in *B. subtilis* began to resolve in 2005, when the first RNase J enzymes were identified. *B. subtilis* contains two RNase J enzymes, the essential RNase J1 and the nonessential RNase J2, which are similar in size and share 49% identical residues. In a strain with no RNase

J2 and a fivefold lower RNase J1 activity than wild type, the level of hundreds of mRNAs is increased or decreased significantly. Most bacterial species have either an RNase E or an RNase J family enzyme, but not both. RNase J1 of *B. subtilis* is, so far, the most well-studied RNase J family member. Like RNase E, RNase J1 is believed to be a 5'-end binding enzyme. However, unlike RNase E, the endonuclease activity of RNase J1 is effective on substrates with either 5'-monophosphate or 5'-triphosphate ends.

RNase J1 is also a 5'-to-3' exoribonuclease

The finding of RNase J1 endonuclease activity, which may be responsible for initiation of decay in *B. subtilis*, was followed (in 2007) by the remarkable discovery that RNase J1 is not only an endonuclease but also a 5' exonuclease, the very activity that was thought not to exist in bacteria. Thus, RNase J1 is a dual-acting ribonuclease, with both endonuclease and exonuclease activities – a rare enzyme in biology. Unlike the endonuclease activity of RNase J1, which is insensitive to the 5'-end phosphorylation state, the exonuclease activity of RNase J1 absolutely requires a 5'-monophosphate end. The reason for this restriction is clear from the crystal structure of an RNase J enzyme, which shows a 5'-end binding site that can accommodate a monophosphate (but not a triphosphate) nucleoside and that sits a one-nucleotide distance away from the catalytic site. This arrangement perfectly explains the 5'-exonuclease activity of RNase J1 and its sensitivity to 5'-end phosphorylation. However, at this time, it is unclear how RNase J1 endonuclease activity is achieved, as biochemical experiments indicate that the identified catalytic site is used for both exonucleolytic and endonucleolytic cleavage.

Other Endoribonucleases

RNase III is an endonuclease that recognizes specific double-stranded RNA structures. RNase III family enzymes are ubiquitously expressed in bacteria and even in higher eukaryotes, where the RNA_i enzyme known as dicer is an RNase III family member. RNase III's major function is in processing of stable RNAs, and it does not appear to play a significant role in the initiation of mRNA decay, other than a single known example of a particular operon mRNA and the examples of ribonuclease gene regulation cited below.

A very recent discovery in *B. subtilis* is the essential endonuclease RNase Y. A mutant *B. subtilis* strain, which contains lower than normal levels of RNase Y, shows a twofold increase in global mRNA half-life, indicating a significant impact of this enzyme on mRNA decay. It is expected that future studies will reveal an important role for this new enzyme in mRNA decay, in the diverse bacterial species that carry it.

Oligoribonuclease

3' Exoribonucleases can digest long polyribonucleotides in a processive manner, that is, the enzyme binds to the 3' end of the RNA and catalyzes phosphodiester bond cleavage to liberate successive end-nucleotides without releasing the substrate. As the length of the substrate becomes shorter than approximately 12 nucleotides, the reaction becomes distributive, that is, the enzyme releases the substrate and randomly binds a

3' end. Chains that are only 2–4 nucleotides long are no longer substrates for 3'-exoribonuclease activity, and they accumulate in *in vitro* reactions. Such accumulation could not occur *in vivo*, however, where RNA substrates need to be turned over completely to mononucleotides in order to maintain the ribonucleotide pool that is used for new RNA synthesis. Thus, bacteria have a specialized, essential 3' exonuclease called oligoribonuclease, which is able to digest very short oligonucleotides to completion (see Figure 1).

Comparison of Models for mRNA Decay

The existence of a 5'-exonuclease activity in *B. subtilis* has stimulated new models for initiation and complete turnover of an mRNA. Figure 1 shows a comparison of models for mRNA decay in *E. coli* (discussed in detail earlier) versus *B. subtilis* and other RNase J-containing organisms. In the latter case, decay can initiate either by an endonuclease cleavage (Figure 1(b)), right), or by attack from the 5' end (Figure 1(b)), left) if the 5' phosphate has been converted from a triphosphate to a monophosphate end. In addition, endonucleolytic cleavage can be followed by 5'-exonuclease activity that degrades the downstream fragment, including the 3' terminus. It is known that the 5' exonuclease activity of RNase J1 can degrade through secondary structure. It has been hypothesized that the exonuclease activity of RNase J1 is stimulated by prior endonuclease activity. Thus, RNase J1 endonuclease cleavage may be followed by rapid degradation of the downstream product without the release of the substrate. The near future will see more studies in *B. subtilis* aimed at clarifying whether the 5'-exonuclease activity or the endonuclease activity of RNase J1 is essential, and whether RNase Y plays a major role, perhaps even more important than RNase J1.

Regulation of RNase Expression and Activity

As control of mRNA stability is an important element in gene expression, it stands to reason that the activity of enzymes involved in mRNA decay may be regulated. In fact, the key *E. coli* endonuclease, RNase E, autoregulates its expression quite tightly. When the cellular concentration of RNase E increases, the enzyme cleaves *rne* mRNA, resulting in unstable *rne* mRNA and less RNase E translation. Similarly, the narrow-specificity RNase III enzyme autoregulates its own expression by cleaving the 5'-leader region of *rnc* mRNA, leading to mRNA instability and less RNase III expression. Interestingly, cross-regulation of ribonucleases is also known. In *E. coli*, RNase III cleaves in the 5'-proximal region of the *pnp* mRNA, resulting in PNPase-mediated degradation of the 5'-terminal fragment that is bound by complementary base-pairing to the sequence upstream of the PNPase translation initiation region (see Figure 4). This results in access of the 5' end of the downstream fragment to RNase E-initiated decay. Thus, the combined action of three ribonucleases participates in the regulated expression of one of them. Regulation of ribonuclease gene expression is not only at the level of mRNA decay. Another example is the effect of the *gmr* gene product on RNase II activity (*gmr* = gene modulating RNase II). The Gmr protein

Figure 4 Regulation of *pnp* mRNA stability by RNase III, PNPase, and RNase E. The mRNA schematic shows the 5'-proximal secondary structure and the *pnp* coding sequence (open rectangle).

does not affect RNase II mRNA levels but, rather, controls the stability of the RNase II protein itself.

In addition to the regulation of ribonuclease levels, auxiliary proteins are known that bind a ribonuclease and regulate its activity. Two regulators of *E. coli* RNase E have been identified and named RraA and RraB (regulator of ribonuclease activity). These regulators bind at different sites in the C-terminal scaffold region of RNase E and inhibit its activity in specific ways. It will be interesting to determine how the ribonuclease regulators are themselves regulated.

Small Regulatory RNAs

A recent development in RNA biology has been an appreciation of the large number of small RNAs (sRNAs) that function as regulators of gene expression. Dozens of such sRNAs have been found in intergenic regions using bioinformatics approaches, microarray experiments, and deep sequencing. The sRNAs function in several ways to affect gene expression, one of which is to direct decay of one or more target mRNAs, similar to the function of microRNAs in eukaryotic systems. The action of sRNAs is directed by limited or extensive base complementarity between a specific mRNA and an sRNA, and is mediated by Hfq, a small RNA-binding protein that is an obligatory partner in sRNA-mediated decay. Hfq binds to the

Figure 5 sRNA-mediated decay of a specific mRNA via pairing of sRNA to mRNA, binding of Hfq, and recruitment of RNase E.

sRNA and to RNase E to form a complex that is targeted to a specific mRNA (Figure 5). By virtue of its indirect interaction with RNase E (via Hfq), the binding of sRNA causes an increase in the local concentration of RNase E, resulting in a more rapid initiation of decay.

Translation and mRNA Decay

The intimate association of ribosomes and mRNA portends an effect of translation on mRNA half-life. An efficiently translated mRNA will have a high degree of ribosome occupancy, which should provide protection against decay-initiating endonuclease cleavage. However, we know very little about the parameters for steric hindrance to endonucleases that a ribosome flow might provide, and the relationship between translation and mRNA decay is not straightforward. What has been observed in many cases in *E. coli* and *B. subtilis* is that the strength of the ribosome:mRNA interaction at a 5'-proximal RBS can affect mRNA half-life. Thus, for an RBS that is located close to the 5' end, mutations that weaken the rRNA:RBS interaction most often result in destabilization. Similarly, mutation of the start codon to a codon that does not function in translation initiation results in a decrease in mRNA stability. It is thought that efficient and tight binding of the ribosome to the RBS restricts access to the 5' end by a decay-initiating endonuclease. In accordance with this hypothesis, the stabilizing effect of a favorable rRNA:RBS interaction is abolished when the RBS is located some distance away from the 5' end. What is less clear is the effect of a premature stop codon. In some cases in *E. coli* (but not all), insertion of a premature stop codon causes destabilization. Thus, in addition to ribosome binding near the 5' end, a flow of ribosomes down the body of the message seems to be required for optimal stability. On the other hand, experiments done on a limited number of *B. subtilis* mRNAs have shown that inserting an early stop codon, even immediately after the start codon, has no effect on mRNA half-life. Whether or not ribosome flow is relevant to stability could depend on where the initial endonuclease cleavage occurs; that is, if this cleavage occurs upstream of the

coding sequence, then ribosome flow in the coding sequence may not affect stability, as the initial cleavage will generate a new 5' end that promotes efficient decay, even in the presence of ribosome flow. However, if the initial cleavage occurs in the coding sequence itself, the presence of closely spaced ribosomes could inhibit initiation of decay.

We mentioned earlier the fascinating tmRNA system, which is used by cells to offload ribosomes that have reached the end of a nonstop mRNA. The tmRNA–protein complex includes RNase R, which degrades the nonstop mRNA in the 3'-to-5' direction. A nonstop mRNA can be generated by a decay-initiating endonuclease cleavage, or as a consequence of ribosome pausing during translation, which occurs at particular sequences/structures and under amino acid starvation conditions. Ribosome pausing activates a ribosome-bound mRNA interferase, which cleaves the codon that occupies the ribosomal A site, generating a nonstop mRNA from which the ribosome is offloaded by tmRNA and which is degraded by RNase R. There is also a second class of mRNA interferases, which function in a ribosome-independent manner. These mRNA interferases are activated under stress conditions, and they cleave mRNA endonucleolytically in a site-specific manner (e.g., at every ACA triplet sequence). The degradation

of mRNAs by mRNA interferases results in bacteriostasis, allowing the cell to survive the stress condition.

Glossary

Alternative splicing A process through which a given primary transcript undergoes differential exon joining events to produce mature messenger RNAs (mRNAs), in which some segments differ; in most cases, these mRNAs are translated to yield proteins that may have different properties.

Chromatin The complex of genomic DNA and its associated proteins present in the nuclei of eukaryotic cells.

Exon A block of sequence within the pre-mRNA that is retained in the mature mRNA following splicing.

Intron A block of sequence within the pre-mRNA that is removed via splicing in the cell nucleus.

5' mRNA capping Addition of 7-methylguanosine to the 5' phosphorylated end of a nascent RNA polymerase II transcript through an enzymatic mechanism that produces a 5'-5' triphosphate linkage.

mRNA The class of RNA that carries the coding information from the DNA in the nucleus to the cytoplasm and serves as the blueprint for protein synthesis by cytoplasmic ribosomes.

Nucleosome The repeating unit of chromatin, which consists of DNA wrapped around a histone octamer consisting of two copies each of the H2A, H2B, H3, and H4 proteins.

ORF An open reading frame, defined as a continuous segment of nucleic acid that contains no nonsense codons and, therefore, can be translated into a full-length polypeptide.

Pre-mRNA The primary transcript of a gene synthesized by RNA polymerase II, which serves as the substrate for

RNA-processing reactions. Primary transcripts, also known as precursor mRNAs, extend from the site of transcription initiation to beyond the 3' end of the mature mRNA.

Ribonucleoprotein particle A general term used to describe any complex of RNA and protein.

RNA polymerase II The eukaryotic enzyme that catalyzes synthesis of mRNA precursors as well as a subset of small stable RNAs.

RNA splicing A process by which primary transcripts are converted to mature mRNAs via the removal of internal segments known as introns accompanied by precise joining of exons.

snRNP An acronym for small nuclear ribonucleoprotein particle, generally used to describe complexes between one or two small stable RNAs and a variable number of proteins; these reside in the cell nucleus and function in RNA-processing reactions.

Spliceosome A macromolecular complex composed of snRNPs and proteins that assembles on pre-mRNAs and catalyzes the splicing reaction.

3' mRNA polyadenylation Addition of multiple adenosine monophosphate (AMP) units derived from adenosine triphosphate (ATP) to the 3' end of a nascent RNA by poly(A) polymerase at a site created by cleavage of the precursor RNA. The cleavage/polyadenylation site is defined by specific 3' signals recognized by components of the polyadenylation machinery other than the polymerase.

Transcription The process through which RNA is synthesized in the cell nucleus by enzymes known as RNA polymerases, which copy the DNA template.

Historical Overview

In prokaryotes, all steps in gene expression take place in the same cellular compartment and, thus, transcription and translation of a messenger RNA (mRNA) are intimately linked, whereas in eukaryotes, the nuclear membrane provides a physical barrier between the compartments in which an mRNA is synthesized and translated. During its sojourn in the nucleus, the primary RNA transcript undergoes many physical transformations including 5' capping, removal of internal, noncoding sequences via splicing, and addition of a 3' poly(A) tail. Capping, the enzymatic addition of a 7-methyl guanosine not encoded in the DNA to the 5' end of the transcript, occurs very early in the biosynthesis of an mRNA; this modification confers resistance to nucleases that degrade RNA in a 5'-3' direction and also facilitates translation. The poly(A) tail, which can reach lengths of several hundred nucleotides in mammals, is also not encoded in the DNA. Like the cap

structure, the poly(A) tail enhances RNA stability and promotes translation in the cytoplasm; these functions require binding to the major poly(A)-binding protein (designated PAB1 in yeast and PABPC in mammals). The third major nuclear event, pre-mRNA splicing, is the process by which internal noncoding segments (introns) are removed from the primary transcript through a concerted mechanism that concomitantly joins the segments that form the mature mRNA (exons). Finally, some pre-mRNAs are subject to editing, a process through which the sequence encoded in the DNA is altered in the RNA. The ultimate fate of a eukaryotic mRNA is to be degraded (turned over), which generally occurs in the cytoplasm after it undergoes multiple rounds of translation. Throughout its life cycle, a given mRNA is subject to quality-control processes known as RNA surveillance, which detect aberrant processing or damage and target nonfunctional RNA molecules for elimination, in some cases before they can be exported from the nucleus.

Figure 1 (a) Degeneracy of mammalian splicing signals. An internal portion of a pre-mRNA is shown with the consensus sequences flanking the middle exon indicated. (b) Consequences of mutating the 5' splice site in a mammalian pre-mRNA. In the vast majority of cases, the outcome is skipping of the preceding exon (left side), consistent with splice site pairing via exon definition. In rare cases, generally involving small introns that resemble those found in simpler eukaryotes, the intron is retained. (c) Composition of an exon definition complex. The functions of individual proteins are discussed under the section The Roles of RNA-Binding Proteins in the Life Cycle of an mRNA. BBP, branchpoint-binding protein; U2AF, U2 snRNP auxiliary factor, composed of a large and a small subunit; SR, serine-arginine-rich protein; U1, U1 snRNP. The drawing is not to scale.

For a number of years after the cap structure and poly(A) tail were identified and characterized, it remained unclear why cytoplasmic mRNAs were so much smaller than their nuclear precursors, especially in mammalian cells. This mystery was solved by the discovery of premessenger RNA (pre-mRNA) splicing in the late 1970s. The presence of introns was initially revealed by an electron microscopic technique that demonstrated covalent joining at the RNA level of discontinuous gene segments. Soon after the discovery of pre-mRNA splicing, conserved RNA sequence motifs were noted at the exon/intron boundaries and just upstream from the 3' splice site, although their significance did not become clear until elucidation of the splicing mechanism in the early 1980s. Despite the relatively simple chemistry of splicing, the reactions take place in a very large complex dubbed the spliceosome. At the heart of this macromolecular machine are four small nuclear ribonucleoprotein particles (abbreviated snRNPs and pronounced 'snuRPs'), each of these contains one or two snRNA molecules and a variable number of proteins. During the course of spliceosome assembly, the snRNA components recognize splicing signals via base-pairing interactions. At the 5' exon-intron boundary, a hexanucleotide (GUAAGU in yeast) is recognized early in the pathway by U1 snRNA, which is subsequently replaced by U6 snRNA. At the branch site, so named because it is joined to

the 5' splice junction during the first step of splicing to form a lariat structure, is a heptanucleotide (UACUAAAC in yeast) that is complementary to U2 snRNA. The 3' intron-exon boundary, which is joined to the 5' splice junction during the second step of splicing, is demarcated by the trinucleotide YAG preceded by a more variable element (U-rich in yeast). Finally, the moderately conserved nucleotides immediately surrounding the intron form base pairs with U5 snRNA. Although the yeast consensus splicing signals function optimally in mammalian cells, the actual 5' and 3' splice sites are often highly degenerate, with only the terminal GU and AG serving as invariant anchors and the branchpoint motif sometimes barely recognizable (Figure 1(a)). Beyond their roles in splice site recognition, a growing body of evidence indicates that the RNA components of two spliceosomal snRNPs, U2 and U6, are responsible for catalyzing the sequential transesterification reactions through which introns are removed and exons are ligated.

The Relationship between RNA Processing and Organismal Complexity

When the RNA-processing field was in its infancy, splicing was widely believed to make only a minor contribution to either regulated or constitutive gene expression. However, its status was greatly elevated upon completion of the human genome sequence, which revealed far fewer protein-coding genes than expected. The number of distinct proteins necessary to make up a human being is estimated at >100 000; remarkably, these are produced from only ~25 000 genes. Instead of creating entirely new open reading frames (ORFs), the necessary complexity was achieved largely through alternative splicing, a process through which the same genetic information is used to produce multiple functional mRNAs and, therefore, multiple distinct proteins. Although pre-mRNA splicing plays a pivotal role in both regulated and constitutive expression of genes in other eukaryotes, the discrepancy between genome size and the number of protein-coding genes is not nearly so great as in humans. For example, the fruit fly haploid genome contains only ~1/20th the amount of DNA as the human haploid genome but the number of genes is ~13 000, and even the lowly nematode worm has ~18 000 distinct ORFs. Similar to humans and other vertebrates, these invertebrates use alternative splicing to increase the coding capacity of their genomes; in fact, the most complex gene yet to be identified is fruit fly Dscam (Down syndrome cell adhesion molecule), which has the capacity to produce tens of thousands of alternative mRNAs. In contrast to metazoans, unicellular eukaryotes do not make wide use of alternative splicing, and the number of protein-coding genes is similar to the number of proteins, ~6000 in budding yeast and just over 5000 in fission yeast.

Although alternative splicing of human genes is believed to be the primary factor that accounts for the discrepancy between the number of genes and the number of proteins, other processes also contribute. First, alternative polyadenylation or a competition between splicing and polyadenylation within the terminal exon can produce different protein isoforms, and another source of proteomic diversity is editing, a

process in which the sequence of the gene is altered at the RNA level to either change the encoded amino acid or alter the length of the ORF by the introduction or elimination of a nonsense codon. Like splicing, RNA editing often occurs in a tissue-specific manner to produce different forms of the gene product. Finally, the use of alternative promoters can sometimes result in the presence or absence of new exons, but more often alters the length of the 5' untranslated region (UTR) of an mRNA; this, in turn, can affect translation through protein binding or the presence of RNA secondary structure. Similarly, alternative polyadenylation most often changes the length of the 3' UTR, which frequently contains elements that regulate translation and/or stability of the mRNA. By contrast, alternative splicing most commonly results in the inclusion or exclusion of a segment within the protein-coding region, though even in simple eukaryotes introns are sometimes present in the UTRs. A recent estimate suggests that only ~2% of the human genome is utilized to produce protein-coding mRNAs. Of this fraction, the ORFs constitute only ~1/2, with the remainder devoted to the 5' and 3' UTR's.

A Daunting Challenge: Finding Exonic Islands in a Sea of Intronic RNA

Exon Definition

Although the human genome does contain vast regions that largely or completely lack genes, a substantial fraction of the excess DNA is actually copied to produce the primary transcripts that are processed into mature mRNAs for export to the cytoplasm. Given that virtually every mammalian gene contains multiple introns, and that in general these are much larger than the exons that make up mRNAs (Figure 2(a)), a key question was how the small islands of coding RNA are accurately identified and precisely joined. An important clue came from the consequences of splice site mutations: if either the 5' splice site preceding an exon or the 3' splice site immediately downstream sustains a mutation that renders it nonfunctional, the result in the vast majority of cases is skipping of the exon (Figure 1(b), left side) rather than retention of the intron (Figure 1(b), right side). This surprising observation led Susan Berget to propose the 'exon definition' model, which

Figure 2 (a) (Top) Architecture of a typical mammalian primary transcript. On average, pre-mRNAs contain eight exons that are quite uniform in size, clustering around 300 nucleotides, interrupted by seven introns that are generally 1.5–3 kilobases in length but may be as long as half a megabase. Also indicated is the polyadenylation site located near the 3' end of the transcript. (Bottom) The fully processed mRNA after intron removal by splicing and addition of the 5' cap structure and 3' poly(A) tail. (b) Evolution of an alternatively spliced exon from an intronic region. The locations of sequences resembling canonical splicing signals are indicated by AG and GU dinucleotides; acquisition through mutation of a pair of splice sites at a distance that allows recognition by the splicing machinery can lead to exonization of a segment in the pre-mRNA that is part of an intron in the otherwise identical transcript depicted in (a). Inclusion of the alternative exon can be increased by improving the match between its splicing signals or acquisition of a nearby exonic splicing enhancer.

postulates that splice site pairing in mammalian pre-mRNAs initially occurs across the exons. Direct experimental support for this model came from the finding that at the earliest stage of spliceosome assembly, a serine-arginine-rich (SR) protein bridge links the factors bound to the 3' and 5' splice sites on opposite sides of an exon (Figure 1(c)). In simpler eukaryotes, introns are generally much smaller than exons and the splice sites are paired via intron definition, consistent with the finding that splice site mutations generally lead to intron retention. The unifying feature is that in both cases proximity is the driving force for splice site pairing. The exon definition model also helped to explain why, in humans and other higher eukaryotes, exon length is much more uniform than intron length, as well as how exon skipping is generally avoided in spite of the extremely large sizes of many mammalian introns.

Ancillary RNA-Processing Signals

Because unambiguous specification of splice sites is essential to avoid producing mRNAs with frameshifts that would preclude translation into functional proteins, the low information content of mammalian splicing signals was initially puzzling, particularly in light of the frequent occurrence of sequences related to authentic splicing signals within the very large introns. The mystery of the missing splicing information was solved by the discovery of ancillary splicing signals that function in collaboration with the degenerate 'classical' splicing signals (Figure 3(a)). The first group of elements to be discovered, the so-called exonic splicing enhancers, activates weak (i.e., nonconsensus) splice sites via binding to positively acting factors (discussed further below). Subsequently, different classes of splicing enhancer elements were found within introns, and multiple families of elements that repress splicing, known as silencers, can also affect the composition of the mRNA from either exonic or intronic locations. Although enhancers were initially uncovered based on their roles in promoting tissue- or

developmental stage-specific alternative splicing, they also function during constitutive splicing to ensure that exons surrounded by suboptimal splicing signals are included in the mature mRNA. Indeed, the mode of exon recognition in constitutively spliced pre-mRNAs provides the mechanistic basis for positive and negative regulation of alternative splicing. On an evolutionary scale, the degenerate nature of mammalian splice site sequences provides a source for the creation of new exons from sequences that were previously intronic (Figure 2(b)), prompting the designation of introns as the 'playground of evolution'. Conversely, mutations at ancillary splicing signals (particularly splicing enhancers) can lead to exon skipping and, if fixed in the gene pool, permanent loss. Recent estimates suggest that 60% of mutations that cause human disease do so by affecting splicing, via changes either in ancillary or in classical splicing signals.

Despite dramatic progress in understanding the role of splicing on a genome-wide basis, mechanistic questions still remain. For example, regardless of the initial mode of recognition, splice sites must ultimately be paired across introns (Figure 3(b)) to allow the U2 and U6 snRNAs to carry out their catalytic functions. An important challenge for the future is to learn how the necessary rearrangements occur.

The Roles of RNA-Binding Proteins in the Life Cycle of an mRNA

In addition to the snRNPs discussed above, purification and proteomic analyses of spliceosomes at different stages of the splicing cycle revealed a remarkably large number of protein constituents. Among the >300 polypeptides that copurify with the mammalian spliceosome, many turned out to be factors previously identified through biochemical fractionation of cell-free splicing extracts. These include a heterodimeric protein, which was designated U2 auxiliary factor (U2AF) based

Figure 3 (a) Ancillary splicing signals: ESE, exonic splicing enhancer; ISE, intrinsic splicing enhancer; ESS, exon splice site; ISS, intron splice site. The U1 and U2 snRNPs are indicated by cyan and purple balls, respectively, and the effect of each auxiliary splicing element is indicated by a positive or negative symbol. (b) Exon juxtaposition. Before splicing can occur, several poorly understood rearrangements must occur such that the exons are juxtaposed and the catalytic components of the spliceosome (believed to reside within the U2 and U6 snRNP; see text) are positioned across the intron rather than the exon.

on its role in promoting addition of the U2 snRNP to the growing spliceosome. During the earliest phase of spliceosome assembly, the large and small subunits of U2AF recognize the polypyrimidine tract and 3' AG dinucleotide, respectively (Figure 1(c)). The large subunit makes contacts with the branchpoint-binding protein, which is subsequently displaced by the U2 snRNP, while the small subunit forms the 5' anchor of a bridge to the U1 snRNP bound to the downstream 5' splice site. The final constituents of the exon definition complex are the SR family of splicing factors, which form a bridge across the exon. In general, these factors associate with splicing enhancer elements and, in at least some cases, function to promote binding of U2AF, and ultimately U2 snRNP, to the upstream 3' splice site. The roles of splicing silencers are less well understood, but splicing repression has often been associated with members of the heterogeneous ribonucleoprotein family of proteins, members of which also copurify with spliceosomes. Finally, it is important to note that, although the chemical reactions are almost certainly RNA-catalyzed, many proteins also play critical roles in splicing. The most highly conserved of these, a very large protein known as PRP8, makes contact with both the 5' and 3' ends of the introns and remains associated throughout the catalytic cycle.

Many of the proteins implicated in splicing as well as other aspects of RNA metabolism contain domains that recognize short, moderately conserved motifs. The largest group of sequence-specific RNA-binding proteins, designated the RNA recognition motif family, is encoded by over 500 different genes in mammalian cells. Other common RNA-binding motifs include the KH domain, the double-stranded RNA-binding domain, zinc fingers, RGG boxes, and the Pumilio domain. The proliferation of RNA-binding proteins, even in simple eukaryotes, reflects the fact that, throughout its life cycle, an mRNA is associated with a diverse array of proteins, some of them stably bound and others subject to dynamic exchange. In many cases, the protein components of messenger RNPs (mRNPs) serve as adaptors to facilitate association with the macromolecular machines that process it in the nucleus, use it as a blueprint for protein synthesis in the

cytoplasm, or cause its demise via RNA turnover once its useful lifetime has ended.

Mechanistic Coupling of Different Steps in Gene Expression

Until recently, the multiple events required for the production of a translation-competent mRNA from a primary transcript in the nucleus were generally studied in isolation, often in cell-free extracts. Nevertheless, there were early indications that splicing occurs cotranscriptionally *in vivo*, for example, the Beyer laboratory's pioneering electron micrographic studies. Multiple instances in which the same protein was isolated as a splicing factor in one laboratory and a transcription factor in another provided further circumstantial evidence for coupling, but it was not until the late 1990s that the underlying mechanisms began to emerge (Figure 4). A landmark study from the Bentley laboratory used a drug to inactivate endogenous RNA polymerase II (RNAP II) in cells carrying a drug-resistant mutant lacking the C-terminal domain (CTD). Analysis of transcripts made by the mutant polymerase revealed that the CTD is required for both splicing and polyadenylation. The extended structure of this domain, in conjunction with the changes in association of RNA-processing factors due to altered CTD phosphorylation, led to a widely accepted model in which it serves as a recruiting platform at the promoter for delivery of bound factors at appropriate times during the transcription cycle (Figure 4). Remarkably, in addition to capping and splicing factors, factors required for cleavage and polyadenylation to form the mature 3' end of the mRNA are also present at the promoter. Although it has long been known that 3' processing is tightly coupled to transcription termination by RNAP II, the mechanism has been controversial. Recent studies provide support for the so-called 'Torpedo' model, in which degradation of the RNA downstream from the polyadenylation site helps to displace the polymerase from the DNA.

In addition to coupling between RNA processing and transcription, many links have been uncovered between different

Figure 4 'Assembly line' view of cotranscriptional RNA processing. Each stage of RNA polymerase II transcription is indicated at the top, while the next line shows the coupled RNA-processing events that occur during maturation of the primary transcript. RNAP II is indicated by the blue oval with the C-terminal domain (CTD) of its largest subunit indicated by a tail. The capping enzymes are indicated by a green triangle, the spliceosome by a purple pentagon, and the polyadenylation complex by a turquoise hexagon. For simplicity, the complete machinery involved in each step of RNA processing is shown assembled on the CTD at the promoter; in reality, only a subset of the factors, as yet not fully defined, associate with the promoter. Soon after transcription initiation, the 5' end of the nascent RNA acquires a cap, which associates with a heterodimeric protein that stimulates splicing. Spliceosome assembly on the nascent RNA occurs during the transcription elongation phase and, for longer transcripts, introns near the 5' end are spliced out before synthesis of the primary transcript is completed. Processing at the 3' end by cleavage and polyadenylation is coupled to transcription termination.

RNA-processing reactions. For example, both capping and polyadenylation stimulate splicing, and splicing factors have been implicated in RNA export, as has polyadenylation of the newly synthesized RNA. In some cases, the crosstalk is bidirectional; for example, increased transcription stimulates splicing and the presence of a functional 5' splice site promotes RNA synthesis. Perhaps most remarkable is the ability of the exon junction complex, which is deposited on the RNA during splicing in the nucleus, to influence turnover of the RNA in the cytoplasm.

Future Directions

An area that has recently come under intense scrutiny is how the structure of chromatin, the actual template for transcription, affects RNA-processing events. Although it is now clear from both genome-wide studies and investigation of individual genes that histone modifications and chromatin-remodeling factors influence splicing, elucidating the underlying mechanisms will undoubtedly be a fertile area of investigation in the years to come.

Metabolic Control during Ischemia of the Heart

J R Ussher and G D Lopaschuk, University of Alberta, Edmonton, AB, Canada

Glossary

Cardiac efficiency The ratio of external cardiac power to energy expenditure by the left ventricle.

Ischemia A restriction in blood supply.

Reperfusion Restoration of blood flow/supply.

Cardiovascular disease is now the primary cause of death worldwide. For the majority of people living with cardiovascular disease, the underlying cause is a condition coined ischemic heart disease. Ischemia of the heart occurs when coronary blood flow is inadequate, and hence the oxygen supply to the myocardium is not sufficient to meet the oxygen demand of the heart. Due to the heart's high demand for energy to drive cardiac contraction, the heart is extremely susceptible to injury if an interruption to its oxygen supply occurs. The manifestations of myocardial ischemia depend upon the nature and severity of the ischemic episode, and the subsequent re-establishment of flow (reperfusion). Clinically, ischemic heart diseases can manifest as angina pectoris, acute myocardial infarction, and heart failure.

In the aerobic heart, energy production and cardiac function are closely matched. However, ischemia disturbs the relationship between fatty acid and glucose metabolism. In isolated working heart studies, metabolic disturbances during ischemia include an acceleration of anaerobic glycolysis, and of what residual oxidative metabolism remains, a greater reliance of the heart on fatty acids as a fuel source, which occurs at the expense of glucose. This results in an uncoupling between glycolysis and glucose oxidation, which leads to the production of protons and development of intracellular acidosis. As a result, adenosine triphosphate (ATP) must be diverted away from contractile function in order to re-establish ionic homeostasis, which decreases cardiac efficiency.

During successful reperfusion of the ischemic heart, glycolytic rates remain high, and the oxidation of fatty acids quickly recovers, once again at the expense of glucose. Thus, ATP must continue to be used to deal with the intracellular acidosis arising from uncoupled glucose metabolism, and cardiac efficiency remains impaired.

The consequences of myocardial ischemia are numerous, and metabolic perturbations with regards to the availability of circulating energy substrates, as well as the subcellular regulation of energy substrate metabolism are important factors underlying some of these consequences. The purpose of this article is to outline the pathways of metabolism in the healthy heart, the metabolic changes that take place in the heart during ischemia, and how they adversely affect cardiac function. In addition, we also highlight how alterations in certain signaling enzymes contribute to these ischemic-induced changes in metabolism. Finally, we will touch upon studies in both rodents and humans showing that modulating these metabolic disturbances is a novel and promising therapeutic approach for ischemic heart disease.

Carbohydrate Metabolism in the Heart

The primary carbohydrate used as an energy source by the heart is glucose, and the majority of glucose that the heart metabolizes is obtained from the blood with its uptake being facilitated by glucose transporters (GLUTs). GLUT1 is responsible for maintaining basal glucose uptake, whereas GLUT4 translocates from an intracellular pool to the sarcolemmal membrane in response to insulin, increased work demand, or ischemia.

The metabolism of glucose (Figure 1) can be separated into two major components, glycolysis and glucose oxidation. Glycolysis results in the production of pyruvate and accounts for less than 10% of the total ATP produced by the aerobic heart. Flux through glycolysis is primarily regulated at the level of phosphofructokinase-1 (PFK1), which is responsible for catalyzing the rate-limiting, irreversible conversion of fructose-6-phosphate into fructose-1,6-bisphosphate. PFK1 is allosterically regulated by the energy status of the cell, with metabolites of low cellular energy levels such as adenosine monophosphate, adenosine diphosphate, and inorganic phosphate increasing its activity, and metabolites of high cellular energy levels such as ATP and citrate decreasing its activity. If glycolysis is coupled to glucose oxidation, the pyruvate generated from glycolysis is converted to acetyl coenzyme A (CoA) (which is subsequently oxidized in the tricarboxylic acid (TCA) cycle) by the enzymatic action of the multienzyme complex, pyruvate dehydrogenase (PDH) (Figure 1). The majority of pyruvate that is not converted into acetyl-CoA will be converted into lactate via the enzymatic activity of lactate dehydrogenase (LDH), but a small fraction (~2–6% in the aerobic heart) will be carboxylated into malate or oxaloacetate and enter the TCA cycle via anaplerosis.

The PDH complex is under tight regulation by an upstream kinase, PDH kinase (PDK), which phosphorylates and inhibits its activity, whereas PDH phosphatase dephosphorylates and increases its activity (Figure 1). There are four PDK isoforms, with PDK4 being the primary isoform in the heart. PDK is positively regulated by acetyl-CoA and nicotinamide adenine dinucleotide (NADH). As mitochondrial acetyl-CoA/CoA and NADH/NAD⁺ ratios are increased by elevated rates of fatty acid β -oxidation, it leads to an increase in PDK activity and a potent inhibition of PDH and glucose oxidation. This reciprocal relationship between glucose and fatty acids for oxidative metabolism was first described by Sir Philip Randle and colleagues in the 1960s and has been termed the Randle cycle. It will be described in later sections how

Figure 1 Energy metabolism in the aerobic heart. In the aerobic heart, energy metabolism is primarily derived from either plasma glucose or nonesterified fatty acids. Glucose is taken up via glucose transporters (GLUTs) such as GLUT4 and undergoes glycolysis to become pyruvate, which is then converted either into lactate and a H⁺, or taken up into the mitochondria and oxidized via PDH to produce acetyl-CoA for the TCA cycle. Fatty acids are primarily taken up via protein-mediated transporters, such as CD36/FAT, and then activated by esterification to CoA via the enzymatic activity of fatty acyl-CoA synthetase (FACS). The activated fatty acyl-CoA is taken up into the mitochondria via CPT 1, whereby it undergoes β -oxidation to produce acetyl-CoA for the TCA cycle. In the aerobic heart, there is a steady balance between the contribution of glucose and fatty acids for oxidative energy production.

this reciprocal substrate cycle is affected by ischemia and contributes to the pathology of ischemic heart disease.

Alternative sources for glucose metabolism outside of plasma glucose include endogenous glycogen stores and lactate. The mobilization of endogenous glycogen stores can generate glucose-6-phosphate, which bypasses the hexokinase reaction of glycolysis. Thus, glycolysis of glycogen-derived glucose-6-phosphate generates three molecules of ATP, as opposed to the two normally seen from glycolysis of glucose taken up from the plasma.

While being a primary end product of glycolysis, lactate from other tissue sources such as the skeletal muscle is also a major energy source for the aerobic heart, and is converted into pyruvate via the enzymatic activity of LDH. The pyruvate

molecule is then oxidized in the same manner that pyruvate generated from glycolysis is, via the enzymatic activity of PDH. It is important to note that although the heart is normally a lactate consumer, during times of metabolic stress (such as myocardial ischemia) the heart becomes a lactate producer.

Fatty Acid Metabolism in the Heart

Fatty acids enter the cardiac myocyte by either passive diffusion or protein-mediated transport across the sarcolemmal membrane (Figure 1). The rate of fatty acid uptake by the heart is primarily determined by the concentration of free fatty acids (FFAs) in the plasma, which can vary over a fourfold range in

healthy humans during the course of the day (~ 0.2 – 0.8 mM). Once transported across the sarcolemmal membrane, fatty acids are subsequently activated by esterification to CoA by fatty acyl-CoA synthetase. This fatty acyl-CoA can either be partitioned into intracellular lipids, such as triacylglycerol, or converted to long-chain fatty acylcarnitine by carnitine palmitoyltransferase 1 (CPT-1) for subsequent oxidation in the mitochondria. The primary fate of fatty acids taken up into the heart is β -oxidation, as studies in humans have shown that 80% of long-chain fatty acids rapidly appear as CO_2 in coronary venous blood.

Fatty acid β -oxidation occurs predominantly in the mitochondria and to a smaller extent in the peroxisomes. As mentioned, for mitochondrial fatty acid β -oxidation to begin, the cytoplasmic long-chain fatty acyl-CoA must first be transported into the mitochondrial matrix through a carnitine-dependent transport system. This carnitine transport system involves three enzymes: CPT-1, carnitine acyltransferase, and CPT-2. Of these three enzymes, CPT-1 is rate limiting in regards to mitochondrial fatty acid uptake and is subject to potent inhibition via malonyl-CoA. Changes in intracellular malonyl-CoA concentrations during ischemia and reperfusion are key determinants regulating flux through both the fatty acid and glucose oxidative pathways.

Once in the mitochondria, β -oxidation repeatedly cleaves off two carbon acetyl-CoA units from fatty acyl-CoA, generating NADH and reduced flavin adenine dinucleotide (FADH_2) in the process. The β -oxidation process involves four enzymatically catalyzed reactions (acyl-CoA dehydrogenase, 2-enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase), with the last step regenerating acyl-CoA for another round of β -oxidation and releasing acetyl-CoA for the TCA cycle. As mentioned earlier, β -oxidation of fatty acids increases the acetyl-CoA/CoA ratio, which inhibits PDH and subsequent glucose oxidation via the Randle cycle, and is a critical component of how ischemic-induced alterations in metabolism contribute toward the pathology of ischemic heart disease.

Energy Metabolism in the Ischemic Heart

Cardiac energy metabolism is drastically altered during ischemia (Figure 2), with the primary effect of ischemia being a lack of oxygen and nutrient supply and decreased clearance of metabolic by-products from the affected region(s) of the heart. During ischemia, there is a rapid acceleration in the conversion of pyruvate to lactate via LDH, which accelerates in an attempt to provide an anaerobic source of ATP to make up for the reduction in oxidative ATP production. As previously alluded to, PFK1 is the rate-limiting enzyme determining flux through the glycolytic pathway, and is allosterically activated by metabolites such as AMP and P_i , both of which are elevated during ischemia. However, as ischemia progresses and becomes more severe, glyceraldehyde-3-phosphate dehydrogenase can become the rate-limiting enzyme of glycolysis, due to the continual buildup of lactate, protons (H^+ s), and NADH in the cytosol, which inhibit its activity. Further progression of ischemia eventually results in reduced glycolytic rates as glycogen content depletes in combination with the reduction

in coronary flow. Moreover, just before irreversible damage takes place as a full-fledged myocardial infarction, PFK1 translocates from the cytosol to the sarcolemmal membrane and is subsequently inactivated.

Although glycolysis can provide a limited amount of ATP during ischemia, the hydrolysis of glycolytically derived ATP in the absence of subsequent pyruvate oxidation leads to an accumulation of lactate and H^+ s, which cause intracellular acidosis and further aggravate the ionic disturbances brought about by ischemia. Thus during ischemia, when glycolysis is accelerated, a greater proportion of ATP hydrolysis must be diverted toward performing chemical work (re-establishing ionic homeostasis) rather than maintaining contractile function, which is already jeopardized. It should be noted that the accumulation of lactate and H^+ s is less of an issue if the cardiac myocyte is exposed to hypoxia or a very mild ischemia, as opposed to a severe ischemia, since these by-products of glycolysis are rapidly removed from the cardiac myocyte.

When considering the effects of fatty acids on the heart during and following ischemia, it is important to recognize that fatty acids can have differing effects depending on whether the myocardium is hypoxic or ischemic. The obligate requirement for oxygen in the process of oxidative phosphorylation results in a rapid decrease in ATP production from the catabolism of fatty acids and pyruvate in proportion to the degree of ischemia. However, fatty acid β -oxidation dominates as the major source of residual oxidative metabolism with no increase in the relative contribution of carbohydrate oxidation. This contributes to the uncoupling between glycolysis and glucose oxidation, further aggravating intracellular acidosis and dysregulated ionic homeostasis.

With total ischemia there is an accumulation of reducing equivalents in the form of NADH and FADH_2 . Both the acyl-CoA dehydrogenase and 3-hydroxyacyl-CoA dehydrogenase enzyme reactions of fatty acid β -oxidation are sensitive to the redox state of the matrix (NAD^+/NADH and FAD/FADH_2 ratio). The inhibition of fatty acid β -oxidation secondary to the accumulation of reducing equivalents can result in the accumulation of fatty acid intermediates in distinct cellular compartments. Fatty acylcarnitine species can accumulate in both the mitochondrial matrix and cytosol, whereas fatty acyl-CoA species accumulate primarily in the mitochondrial matrix as this pool of CoA does not exchange with the relatively small cytosolic CoA pool. The accumulation of these acylcarnitine and acyl-CoA esters promotes disruption of mitochondrial cristae and the formation of amorphous intramitochondrial densities, changes that may ultimately disrupt mitochondrial function.

Ischemic-Induced Alterations in Metabolic Signaling

The aforementioned changes in metabolism that take place during ischemia are influenced by a number of signaling enzymes (Figure 3). One of the most important signaling enzymes that contributes toward the ischemic-induced elevation of glycolytic rates in the heart is 5'AMP-activated protein kinase (AMPK). AMPK is generally considered to be a cellular energy gauge whose activity reflects the energy status of the cell. During ischemia, the rapid increase in intracellular AMP

Figure 2 Energy metabolism in the ischemic heart. During ischemia, energy metabolism is drastically altered, as lack of oxygen leads to a dramatic reduction in oxidative energy production. However, fatty acids remain the primary source of what residual oxidative metabolism remains. To compensate for the reduction in oxidative energy production, rates of glycolysis are enhanced to provide an anaerobic source of energy. However, because glucose oxidation is impaired, one has an increased conversion of pyruvate into lactate and H^+ s, which results in the development of intracellular acidosis, reducing cardiac efficiency.

concentrations results in a rapid activation of AMPK, which then contributes to the ischemic-induced increase in glycolysis by phosphorylating PFK2 at serine residue 466, increasing PFK2 activity. PFK2 converts fructose-6-phosphate into fructose-2,6-bisphosphate, which is a potent allosteric stimulator of PFK1 activity. Furthermore, increased AMPK activity has been linked to GLUT4 translocation and increased glucose uptake, which would also contribute to the elevated rates of glycolysis observed during glycolysis.

The activation of AMPK during ischemia also results in the phosphorylation and subsequent inactivation of acetyl-CoA carboxylase (ACC), which is the enzyme responsible for the synthesis of malonyl-CoA. This reduction in malonyl-CoA content likely contributes to fatty acid β -oxidation rates accounting for the majority of residual oxidative metabolism observed during ischemia.

Hypoxia-inducible factor-1 α (HIF-1 α) is a transcription factor whose expression is rapidly induced during ischemia in the heart, and its target transcripts include a number of genes involved in the glycolytic pathway such as hexokinase and PFK1/2. HIF-1 α has also recently been shown to increase the expression of PDK1, which would inactivate PDH and further contribute to fatty acid β -oxidation dominating as the major source of residual oxidative metabolism.

Signaling changes in other tissues may also affect metabolism in the heart during ischemia. In particular, ischemia rapidly increases catecholamine discharge, and plasma norepinephrine concentrations increase within minutes and can remain elevated for periods of up to 20 h, depending on the severity of the ischemic insult and ensuing stress response. This activates hormone-sensitive lipase in the adipose tissue and elevates circulating FFA concentrations by promoting

Figure 3 Signaling changes during ischemia that affect energy metabolism in the heart. During ischemia, AMPK is rapidly activated, which increases GLUT4 translocation and activates PFK2. Changes in both of these contribute to the elevation of glycolytic rates observed during ischemia. Furthermore, AMPK activation results in the inhibition of ACC which decreases malonyl-CoA content and contributes to fatty acid oxidation rates dominating as the primary source of residual oxidative metabolism during ischemia. HIF-1 α is also rapidly activated during ischemia, and this transcription factor increases the transcription of a number of glycolytic enzymes such as hexokinase and PFK1/2. In addition, HIF-1 α also increases the transcription of PDK1, which like AMPK's effect on ACC, contributes to fatty acid oxidation rates dominating as the primary source of residual oxidative metabolism during ischemia.

lipolysis. Furthermore, elevated plasma concentrations of hydrocortisone accompany the stress of ischemia, having permissive effects on adipose tissue lipolysis. An increase in circulating plasma FFAs during and following ischemia thus increases the delivery of fatty acids to the heart and can alter fatty acid utilization during both the ischemic and postischemic period.

In total, all these signaling changes collectively result in a dramatic increase in glycolysis to compensate for the reduction in oxidative energy metabolism, and due in part to the Randle cycle, a reliance on fatty acids for what residual oxidative metabolism remains. This leads to the uncoupling of glycolysis from glucose oxidation, which results in the production of H^+ s and induces intracellular acidosis, reducing the efficiency of converting metabolism into contractile function.

Energy Metabolism during Reperfusion of the Ischemic Heart

During reperfusion of the ischemic heart, glycolytic rates remain high, while fatty acid β -oxidation rates recover to a greater extent than that of carbohydrates such as glucose (Figure 4). As mentioned in the previous section, this likely arises from elevated circulating FFA concentrations due to sympathetic nervous system activation and catecholamine discharge from the stress of ischemia, and a continued reduction in intracellular malonyl-CoA content. In the rat heart this is accompanied via continued activation of AMPK and subsequent inhibition of ACC, although in the mouse heart AMPK activity and malonyl-CoA content return to preischemic values. Regardless of these species' differences, glycolysis remains dramatically

Figure 4 Energy metabolism in the reperfused heart. In the critical period immediately after successful reperfusion of the ischemic heart, glycolytic rates remain high, while fatty acid oxidation rates rapidly recover. Increased fatty acid oxidation is due in part to decreased malonyl-CoA content. Increased by-products of fatty acid oxidation, such as acetyl-CoA and NADH, activate PDK isoforms such as PDK4, which inhibit PDH and impair the recovery of glucose oxidation rates. Thus, pyruvate from glycolysis is not oxidized via PDH, and once more goes into lactate and H^+ s, intracellular acidosis continues, cardiac efficiency remains impaired, and this limits the recovery of cardiac function.

uncoupled from glucose oxidation in both the rat and mouse heart, H^+ production, and intracellular acidosis ensue, which limits the recovery of cardiac efficiency and function. Recent data in humans support the findings reported in rodents, as use of a comprehensive metabolomics approach revealed that fatty acid extraction persisted as the major fuel substrate contributing to myocardial ATP requirements in patients with coronary artery disease after reperfusion following cardiac surgery versus that in control patients.

Intracellular Acidosis and Cardiac Efficiency during Ischemia/Reperfusion

Cardiac efficiency is defined as the ratio of external cardiac power to energy expenditure by the left ventricle, and as

alluded to throughout this article, the metabolic alterations that take place in the heart during ischemia and reperfusion result in an intracellular acidosis that contributes to a reduction in cardiac efficiency.

The marked decrease in ATP production during ischemia leads to the inhibition of the Na^+/K^+ ATPase, which is responsible for the extrusion of three Na^+ ions in exchange for two K^+ ions and is crucial in regulating resting membrane potential. Impaired function of the Na^+/K^+ ATPase thus results in intracellular Na^+ overload. Impaired activity of the sarcoplasmic Ca^{2+} ATPase, which is responsible for the reuptake of Ca^{2+} following myocyte contraction, contributes to Ca^{2+} overload. As Ca^{2+} is required for cardiac muscle contraction, it is a major determinant of the pathophysiology of ischemic and postischemic contractile dysfunction, via mechanisms involving decreased responsiveness of the contractile proteins to

activator Ca^{2+} . Intracellular acidosis itself impairs the response of the contractile filaments to Ca^{2+} , thereby contributing to the impaired recovery of function during reperfusion. The increased contribution of fatty acid β -oxidation to myocardial energy requirements occurs again at the expense of glucose oxidation during reperfusion, and in conjunction with the alterations in ionic homeostasis occurring during ischemia, primes the myocardium to further injury. The uncoupling of glycolysis from glucose oxidation during the postischemic period results in an increase in H^+ production and produces a large pH gradient across the sarcolemmal membrane, which promotes Na^+/H^+ exchange, further aggravating intracellular Na^+ overload. This in turn promotes reverse mode $\text{Na}^+/\text{Ca}^{2+}$ exchange, and the sequence of events associated with intracellular Ca^{2+} overload, including contracture, mitochondrial dysfunction, the activation of Ca^{2+} -dependent proteases, and cardiac myocyte cell death culminating in the impaired recovery of cardiac function and efficiency.

Optimization of Energy Metabolism to Treat Ischemic Heart Disease

Because the metabolic alterations that take place during ischemia/reperfusion have a major role in determining outcome, a number of studies have attempted to optimize metabolism in the heart as a novel approach to treat ischemic heart disease (see Table 1 for an overview of current metabolic agents and their effects). Via the Randle cycle, a decrease in fatty acid β -oxidation rates leads to a subsequent increase in glucose oxidation rates, which can improve the coupling of glucose metabolism, decrease H^+ production, and therefore increase cardiac efficiency and functional outcome. In addition, the oxidation of glucose produces more ATP per consumption of one oxygen molecule versus the oxidation of a fatty acid such as palmitate, which also contributes to the increase in cardiac efficiency.

Studies in humans have shown that inhibiting fatty acid β -oxidation with agents such as trimetazidine or perhexiline has beneficial effects in the treatment of angina, acute myocardial infarction, and even heart failure. Furthermore, direct stimulation of glucose oxidation with an agent such as dichloroacetate has also shown some benefit in the treatment of heart failure, but it is limited by a very short half-life.

In animal studies, a new approach to optimizing myocardial metabolism is to increase malonyl-CoA content in the heart, which would inhibit fatty acid β -oxidation rates by decreasing mitochondrial fatty acid uptake. This can be achieved by inhibiting malonyl-CoA decarboxylase (MCD), which is the primary enzyme responsible for the degradation of malonyl-CoA. A number of recent studies have shown that MCD inhibition increases malonyl-CoA levels and improves functional outcome during both angina and ischemia/reperfusion injury, which is associated with a significant increase in glucose oxidation rates and a decrease in H^+ production.

Summary

Overall, ischemia of the heart is associated with dramatic alterations in energy fuel metabolism. These metabolic alterations primarily involve a robust increase in glycolysis and a

Table 1 Metabolic agents used to treat ischemic heart disease

Metabolic agent	Metabolic effect	Clinical use
Perhexiline	CPT 1 inhibitor ↓ Fatty acid oxidation rates	Anti-anginal agent since the 1970s – limited clinical use
Trimetazidine	3-Ketoacyl-CoA thiolase inhibitor ↓ Fatty acid oxidation rates	Approved anti-anginal agent in over 80 countries
CBM-301106	MCD inhibitor ↓ Fatty acid oxidation rates	Improves functional recovery against ischemia/reperfusion in rodents No clinical data available
Dichloroacetate	PDK inhibitor ↑ Glucose oxidation rates	Currently under clinical trial Limited to acute use due to short half-life

decrease in oxidative metabolism that depends on the severity of the ischemia itself. However, fatty acids are the preferred substrate for what residual oxidative metabolism remains. These metabolic alterations persist during reperfusion of the ischemic heart, and thus in both scenarios glycolysis is severely uncoupled from glucose oxidation, which culminates in the production of H^+ s and the development of intracellular acidosis. Thus, during both ischemia and reperfusion, ATP is diverted away from the contractile function toward maintaining pH and other ionic disturbances, which impairs the heart's efficiency of converting energy metabolism into mechanical work. This is detrimental to the recovery of the heart during ischemia/reperfusion, and as such, novel therapies for ischemic heart disease are now focusing on optimizing heart metabolism in order to improve cardiac efficiency and function.

Glossary

Adipokine Adipocyte-derived secretory protein. They are important factors for regulating metabolism, inflammation and many other cellular processes.

AdipoR1, AdipoR2 AdipoR1 and AdipoR2 serve as receptors for adiponectin and mediate some of the biological effects of adiponectin.

Lipotoxicity Pathological accumulation of lipids in non-adipose tissues.

LMW, HMW Low- and high-molecular weight complexes of adiponectin.

Thiazolidinediones (TZDs) Synthetic ligands for activation of the nuclear receptor PPAR γ .

Characterization and Molecular Structure

Adiponectin is a circulating hormone secreted predominantly by adipocyte cells. It was originally referred to as adipocyte complement-related protein of 30 kDa (ACRP30), but was later also described as apM1, adipoQ, or GBP28. The molecular weight of the basic monomer is about 30 kDa. It has an amino-terminal signal sequence, a hypervariable region that differs from species to species, a collagenous domain, and a carboxy-terminal globular domain. Many published studies use a recombinant form of the protein that consists of only the globular domain of adiponectin (Figure 1).

In humans and rodents, adiponectin circulates in plasma at approximately $10 \mu\text{g ml}^{-1}$ and therefore contributes approximately 0.01% of total plasma protein. Adiponectin has been shown to play many roles in a plethora of physiological processes. Adiponectin levels in circulation are tightly linked to insulin resistance, obesity, diabetes, and cardiovascular disease. Adiponectin has a complex structure and forms basic homotrimeric building blocks. These trimers associate through disulfide bonds to form higher-order structures, which include low-molecular-weight (LMW) hexamers and high-molecular-weight (HMW) complexes of more than 540 kDa (Figure 2). All three forms are found in circulation in humans, while HMW and LMW forms are the more predominant forms in rodents. Several thousand papers report interesting correlations of adiponectin with a number of parameters reflecting metabolic health. These correlations generally hold up by measuring total plasma adiponectin. However, a number of papers point out stronger correlations of metabolic parameters with specific levels of adiponectin subcomplexes. Particularly, the HMW form of adiponectin has found widespread acceptance as a better correlative factor for insulin sensitivity. Alternatively, the ratio of HMW adiponectin/total adiponectin can also be correlated, in an excellent manner, with various aspects of the metabolic syndrome.

Regulation of Adiponectin Levels

Unlike other hormones such as insulin, the circulating adiponectin levels are tightly controlled and remain relatively stable within a narrow range, suggesting that there is very little tolerance

for fluctuations in plasma adiponectin levels. Normal circulating adiponectin levels range from 5 to $30 \mu\text{g ml}^{-1}$. This is particularly surprising in the light of a relatively rapid turnover of the protein in circulation, with plasma half-lives of 60 min or less. Even though adiponectin is primarily a product of adipocytes, there is a paradoxical decrease of adiponectin in the plasma of obese subjects with higher fat mass. In addition to correlations with total fat mass, adiponectin levels are also affected by body fat distribution. Plasma levels of adiponectin exhibit strong negative correlations with intra-abdominal fat mass. However, *ex vivo* analysis of adipose tissue in lean and obese subjects suggests lower adiponectin protein and mRNA levels in omental versus subcutaneous fat pads. Importantly though, it is unlikely that adiponectin levels in plasma are regulated transcriptionally in adipocytes. In fact, the main regulatory nodes for adiponectin release are likely to be found at the posttranslational level in the secretory pathway. Therefore, it is the rate of adiponectin release from the cells rather than a static mRNA or protein measurement associated with the tissue that is of relevance. Additional clinical studies have been carried out to investigate the effect of lipodystrophy, characterized by adipose tissue loss or adipose tissue misdistribution. The results show that both congenital and human immunodeficiency virus (HIV)-related lipodystrophies are associated with lower adiponectin levels. Treatments that reconstitute normal fat mass also normalize adiponectin levels.

Interestingly, circulating adiponectin and relative levels of the HMW complex are higher in females who have higher levels of body fat mass compared with males. This hints at the complex hormonal regulation of adiponectin that includes effects of estrogen and androgen that exert profound effects on adiponectin levels at various stages of development. There is also a nutritional component involved in the regulation of adiponectin levels, such that diets associated with improvements in insulin sensitivity, such as foods enriched in $\Omega 3$ fatty acids and soy-based diets, lead to higher adiponectin levels. Table 1 summarizes some of the critical factors known to affect adiponectin concentrations in plasma.

Adiponectin Receptors

Several putative receptors have been identified for adiponectin. The biological functions of adiponectin have been postulated

to be exerted mainly through the two main adiponectin receptors referred to as AdipoR1 and AdipoR2. Both AdipoR1 and AdipoR2 are surface membrane proteins with seven transmembrane domains, have similar overall topology, and are both widely expressed in many tissues, including liver, muscle, and fat tissue, with most cell types preferentially expressing one of the receptors more prominently than the other. AdipoR1 has been shown to have a higher affinity for globular adiponectin and is more prominently expressed in skeletal muscle. By contrast, AdipoR2 is a medium-affinity receptor for both globular and full-length HMW adiponectin, more highly enriched in liver. Both AdipoR1 and AdipoR2 are thought to mediate increased AMP-activated protein kinase (AMPK) and peroxisome proliferator-activated receptor alpha (PPAR α) activities, leading to increased fatty acid oxidation and glucose uptake, but much more work needs to be done to better understand the role these receptors play in mediating improvements in insulin sensitivity. The expression levels of AdipoR1 and -R2 are decreased in insulin resistant *ob/ob* mice, as well as in the skeletal muscle of type 2 diabetic patients.

Adaptor protein containing PH domain, PTB domain, and Leucine zipper motif (APPL)1, an adaptor molecule with a pleckstrin homology domain and a phosphotyrosine-binding domain, may be a downstream mediator of activated adiponectin receptors. It has been shown to interact with the intracellular region of AdipoRs, thereby creating a link to AMPK upregulation, glucose uptake, and β -oxidation.

A third receptor has been cloned and shown to be T-cadherin that can mediate adiponectin binding to endothelial cells. It is primarily thought of as a tethering receptor for adiponectin, since T-cadherin lacks an intracellular signaling domain. The more detailed involvement of T-cadherin in adiponectin signaling has yet to be described.

Physiological Functions of Adiponectin

There are a remarkable number of physiological functions that have been attributed to adiponectin. While there is no doubt about the fact that modest changes in adiponectin levels yield remarkable physiological changes, a unifying mechanism of action has yet to be proposed to account for the anti-inflammatory, insulin-sensitizing, anti-apoptotic, and pro-angiogenic actions.

Insulin Sensitivity Effect

One of the most important aspects of adiponectin is its association with improvements in insulin sensitivity. During the past decade, a large number of clinical studies have associated adiponectin as an important factor regulating whole-body insulin sensitivity. Decreased circulating adiponectin is strongly associated with decreased insulin sensitivity under a vast number of pathophysiological conditions. Beyond its usefulness as a mere marker for insulin sensitivity, studies in rodents have demonstrated that the manipulation of adiponectin levels have a direct causative relationship to insulin sensitivity. Adiponectin null mice show decreased hepatic insulin sensitivity, whereas transgenic overexpression of adiponectin or supplying the molecule in a recombinant form enhances insulin sensitivity. These effects are further exacerbated when the mice are exposed to a high-fat diet. The correlations with insulin sensitivity can be further refined both in rodents' and humans' samples by focusing on the relative levels of the three different complexes in circulation. Particularly, the levels of the HMW adiponectin form show improved correlations compared to total adiponectin levels, at least under some physiological conditions or pharmacological interventions. The underlying mechanisms for the improvements in insulin sensitivity remain to be further established, but adiponectin has potent anti-lipotoxic activities on the liver by redistributing hepatic lipids to adipose tissue.

Vasculature and Anti-Atherogenic Effects

Adiponectin has beneficial effects on vascular endothelium. Adiponectin directly stimulates the production of nitric oxide (NO) by endothelial cells, via PI3-dependent pathways, which enhance endothelial NO synthase (eNOS) activity. Apart from the beneficial effects on eNOS, adiponectin improves endothelial redox state by suppressing nicotinamide adenine dinucleotide phosphate oxidase-derived superoxide generation. The HMW adiponectin also suppresses endothelial cell apoptosis and promotes vascular healing and angiogenesis.

Adiponectin may also be protective against the development of atherosclerosis. Adiponectin strongly inhibits the expression of adhesion molecules, including intracellular adhesion molecule-1, vascular cellular adhesion molecule-1, and E-selectin. The inhibition attributes directly to protection effect. In addition to the direct effects of adiponectin on the vasculature system, adiponectin may exert additional anti-atherogenic effects through the modification of lipid metabolism. Adiponectin levels are negatively correlated with serum triglycerides and small dense low-density lipoprotein, and positively correlated with high-density lipoprotein. This leads to the clinically widely studied inverse correlations with cardiovascular disease. High circulating levels of adiponectin are associated with a decreased risk of myocardial infarction in men. Major questions remain in this area, since end-stage cardiovascular disease is associated with a surprising increase in circulating levels of adiponectin. In addition, studies on the anti-atherogenic properties of adiponectin yielded mixed results.

Anti-Inflammatory Effect

Adiponectin reduces expression of pro-inflammatory cytokines, such as tumor necrosis factor (TNF α) and C-reactive protein. It also downregulates the expression of macrophage-attracting adhesion molecules, inhibits the activation of inflammatory signaling cascades, and prevents the production of excessive mitochondrial reactive oxygen species that lead to oxidative stress damage. Clinical observations have demonstrated a strong inverse relationship between serum adiponectin levels and inflammatory markers in a large number of studies. Anti-inflammatory drugs, such as TNF α neutralizing compounds and PPAR γ agonists, increase circulating adiponectin levels.

Adiponectin and Adiponectin Receptors as Therapeutic Targets?

Based on their beneficial effects on many aspects of human physiology, adiponectin and adiponectin receptors may lend themselves as excellent therapeutic targets for the treatment of insulin resistance, inflammation, and cardiovascular disease. Recombinant adiponectin treatment has only been done in preclinical models. Due to its short half-life, high serum concentrations, and complex tertiary and quaternary structure, adiponectin is not an attractive recombinant therapeutic protein. An alternative strategy is to develop agents that may induce adiponectin expression and secretion. To date, the most effective pharmacological intervention resulting in an increase in circulating levels are the PPAR γ agonists (thiazolidinediones (TZDs)). These PPAR γ agonists have been widely used to treat type 2 diabetes. Plasma adiponectin levels, especially HMW adiponectin, dramatically increase in response to TZD exposure. In fact, the full therapeutic potential of these PPAR γ agonists critically depends on their ability to induce adiponectin.

Since AdipoR1 and -R2 are downregulated in the obese and insulin-resistant state, strategies aimed at restoring normal levels of the receptors seem worthwhile. More importantly, small molecule activators of these receptors promise to be a powerful strategy to induce the full activity for these receptors. The screening for small compounds that enhance or mimic adiponectin action through modulation of expression and/or function of either adiponectin or its receptors may therefore represent powerful therapeutic strategies for targeting insulin resistance, type 2 diabetes, metabolic syndrome, and cardiovascular disease.

Glossary

Blood–brain barrier A barrier between circulating blood and the brain that only allows certain substances to pass through and enter the brain.

Central nervous system (CNS) Part of the nervous system that consists of the brain and spinal cord.

Energy homeostasis The biological process whereby energy intake is matched to its expenditure to promote the stability of body fuel stored as fat.

Hyperphagia An increase in food intake.

Insulin resistance A condition in which the normal biological response to insulin is impaired.

Satiety The state of being satisfactorily full.

Introduction

Each of us makes decisions several times per day about whether and when to eat, and how much to eat in any given meal. Although such decisions are often made with little conscious thought, they are nonetheless shaped by a myriad of biological, environmental, and lifestyle factors. Among these are social variables, learned preferences, time of day, emotional state, stress, nutritional status, and the smell, taste, and sight of food. Consequently, both the number of calories consumed in any given meal, and the total calories consumed on any given day can vary considerably. Despite this inherent variability, energy intake is matched to energy expenditure over long time intervals so as to promote stability in the amount of body fuel stored as fat, through a process termed as ‘energy homeostasis’. The central nervous system (CNS) plays a key role in this process through its ability to sense and integrate information from afferent signals regarding energy stores and nutrient availability, and then to orchestrate appropriate adjustments of energy balance. During times of negative energy balance, for example, the brain initiates adaptive metabolic responses to stimulate food intake and reduce energy expenditure that ultimately enable the recovery of lost weight. Presumably arising over millions of years of mammalian evolution, energy homeostasis offers a straightforward and compelling explanation for the frustration experienced by dieters seeking to maintain weight loss achieved through voluntary caloric restriction. Conversely, during times of overnutrition and positive energy balance, the brain initiates biological responses that include reduced energy intake and increased energy expenditure that protect against pathological weight gain. In this overview, we focus on CNS mechanisms that respond to hormonal- and nutrient-related signals involved in energy homeostasis.

Energy Homeostasis

More than 50 years ago, Kennedy first hypothesized the existence of signals that circulate in direct proportion to body fat and act in the CNS to inhibit food intake, thus creating a negative feedback loop to promote stability of body fat mass. Two hormones postulated to act as adiposity signals are the pancreatic β -cell hormone, insulin, and the adipocyte

hormone, leptin. Both hormones circulate at levels proportionate to body adiposity and enter the CNS in proportion to their plasma level. Leptin receptors and insulin receptors are expressed in an overlapping distribution within key brain areas, such as the hypothalamus, which are responsible for the control of food intake and energy expenditure, and the administration of peptide directly into the brain reduces food intake, while promoting increased energy expenditure, thus reducing body weight. Conversely, deficiency of either hormone or its CNS receptor causes hyperphagia and obesity. [Figure 1](#) describes a model in which body adiposity is regulated by a negative feedback loop involving signals that circulate in proportion to body fat, and act in the brain to inhibit food intake and stimulate energy expenditure.

The discovery of leptin and, subsequently, that leptin deficiency causes obesity both in humans as well as mice raised hopes for a new approach to the treatment of human obesity. Most forms of obesity are associated with at least some degree of leptin resistance. Consequently, clinical trials of leptin as a weight-loss agent in obese humans have yielded largely disappointing results. Although several mechanisms have been invoked to explain obesity-associated leptin resistance, including an impaired ability of circulating leptin to either cross the blood–brain barrier or activate its signal transduction pathway, a clear understanding of both the mechanisms underlying this phenomenon and their relevance to obesity pathogenesis is still awaited.

Hypothalamic Neuronal Systems Controlling Energy Homeostasis

Arcuate Nucleus

The hypothalamic arcuate nucleus (ARC) emerged early on as an area of particular importance to energy homeostasis. Situated adjacent to the floor of the third ventricle and the median eminence (a circumventricular organ that lacks a functional blood–brain barrier), ARC neurons can sense and respond to both circulating signals and input from neurons located in other brain areas. Within the ARC are two distinct neuronal populations that exert potent, opposing effects on food intake and energy expenditure in response to a wide assortment of hormonal and nutrient-related inputs.

Figure 1 Negative feedback regulation of body fat mass.

Melanocortin Neurons

Among leptin-sensitive ARC neuronal populations involved in energy homeostasis are those that express proopiomelanocortin (POMC), a precursor polypeptide that is cleaved to generate α -melanocyte stimulating hormone (α -MSH), an agonist of neuronal melanocortin receptors (Mc3r/Mc4r). Activation of these receptors in hypothalamic areas, including the ventromedial and paraventricular nuclei, as well as in brainstem areas such as the nucleus of the solitary tract (NTS), inhibits food intake, increases energy expenditure, and promotes weight loss. A role for melanocortin neurons in energy homeostasis is supported by the observations that (1) these cells are potently stimulated by leptin, (2) leptin-induced weight loss requires melanocortin receptor signaling, and, most importantly, (3) genetic or pharmacological inhibition of POMC neurons or signaling via melanocortin receptors causes obesity in humans as well as in rodent models.

Neuropeptide Y/Agouti-Related Protein Neurons

Adjacent to POMC cells in the hypothalamic ARC is a distinct neuronal subset that expresses two peptides: neuropeptide Y (NPY) and agouti-related protein (AgRP), which promote hyperphagia, positive energy balance, and weight gain. NPY is among the most potent of orexigenic agents and acts via NPY Y1 and Y5 receptors to stimulate food intake. With repeated intracerebroventricular (icv) administration, NPY readily induces obesity and insulin resistance. Also synthesized within these neurons is AgRP, an inverse agonist of Mc3r/Mc4r that reduces endogenous melanocortin signaling. Similar to NPY, central administration of AgRP or pharmacological melanocortin receptor antagonists promotes hyperphagia, weight gain, and insulin resistance. Unlike POMC neurons, NPY/AgRP neurons are inhibited by leptin and insulin (Figure 2). Therefore, in conditions of reduced leptin signaling (e.g., during fasting or diet-induced weight loss), NPY/AgRP neurons are activated, whereas POMC neurons are inhibited, a combination of responses that reduce neuronal melanocortin signaling via multiple mechanisms, thus promoting a state of positive energy balance until lost weight has been recovered. In addition, NPY/AgRP neurons inhibit POMC neurons through release of the inhibitory neurotransmitter γ -aminobutyric acid (GABA), and loss of GABA tone is implicated in the potent

Figure 2 Model for hypothalamic regulation of energy homeostasis. Adapted from Barsh GS and Schwartz MW (2002) Genetic approaches to studying energy balance: Perception and integration. *Nature Reviews Genetics* 3: 589–600, with permission.

anorexia observed following acute, selective destruction of NPY/AgRP neurons in mouse models. These neurons are also targets of several gut-derived peptides, including ghrelin and PYY_{3-36} , and respond to nutrient-related signals, including oleic acid and glucose.

Several observations support a key role for these ARC neurons in energy homeostasis. First, leptin-deficient *ob/ob* mice exhibit sustained hyperphagia associated with reduced hypothalamic expression of POMC messenger RNA (mRNA) and increased expression of NPY and AgRP mRNA, and each of these responses is reversed upon leptin replacement. Second, Mc4r-deficient mice develop a hyperphagic obesity syndrome accompanied by leptin resistance, and the catabolic action of leptin is similarly blocked in normal animals by melanocortin receptor antagonists. Selective leptin receptor deletion from NPY/AgRP neurons also causes excess weight gain (although mild), and selective deletion of insulin receptors from these neurons causes peripheral insulin resistance (mainly at the level of the liver).

Ventromedial Hypothalamus

Brain lesioning and electrical stimulation studies conducted more than half a century ago implicated neuronal populations in the ventromedial hypothalamus (VMH), the lateral hypothalamic area (LHA), and the paraventricular nucleus (PVN) as key areas for food intake control (Figure 3). These classic

studies identified the VMH as a satiety center, as lesions to the VMH resulted in hyperphagia and obesity, while electrical stimulation of the VMH reduced food intake. As leptin receptors are expressed in the VMH and leptin activates neurons in this brain area, the VMH has emerged as a key brain area mediating leptin's anorexic effects. Microinjection of leptin directly into the VMH suppresses food intake, while conversely, selective deletion of leptin receptors from neurons expressing steroidogenic factor-1 (which is expressed selectively by VMH neurons) results in mice with a phenotype characterized by hyperphagia, obesity, glucose intolerance, and insulin resistance. Second, the VMH plays a role in the regulation of melanocortin signaling. Recent evidence suggests that brain-derived neurotrophic factor (BDNF) neurons in the VMH are regulated by both nutritional state, as well as by input from leptin and melanocortin s, and mice with reduced expression of the BDNF receptor, TrkB tyrosine kinase (TrkB), exhibit a phenotype characterized by obesity, hyperphagia, and increased body length, similar to *Mc4r*-deficient mice. In addition, a subset of VMH neurons sends strong excitatory inputs to POMC neurons in the ARC. Taken together, these data suggest that neurons in the VMH are integral components of energy homeostasis that act in part to transduce input from leptin and melanocortins into changes of energy balance.

Lateral Hypothalamic Area

In contrast to the VMH, the LHA is traditionally referred to as a hunger center, as stimulation of the LHA induces food intake, whereas its disruption causes hypophagia and weight loss. Within this brain area are two distinct neuronal populations that are functionally linked to ARC – POMC and NPY neurons – one that expresses melanin concentrating hormone (MCH) and another that produces orexin/hypocretin. Both

neuronal populations are orexigenic, as icv administration of either MCH or orexin stimulates feeding. Similarly, expression of genes encoding both MCH and orexin is increased by fasting and mice deficient in MCH are lean and hypophagic, while targeted deletion of orexin results in narcolepsy, a condition characterized by sudden daytime sleeping, suggesting that orexin signaling also plays a role in sleep, as well as feeding.

Paraventricular Nucleus

In addition to their projections to the VMH and the LHA, NPY/AgRP neurons and POMC neurons in the ARC also project extensively to the PVN, and bilateral PVN lesions cause hyperphagia and obesity, while electrical stimulation of this brain area inhibits food intake. These observations imply the existence of PVN neurons that play a physiological role to inhibit food intake and constrain weight gain. Consistent with this hypothesis, PVN neuronal subsets express both *Mc3r* and *Mc4r*, and several neuropeptides that reduce food intake and body weight, including thyrotropin-releasing hormone (TRH), corticotrophin-releasing factor (CRF), and oxytocin (OXY), are also synthesized in this key brain area. Administration of CRF and OXY into the brain reduces food intake, while leptin-induced anorexia is blocked by administration of either a CRF- or oxytocin-receptor antagonist. Thus, coordinate regulation of the activity of discrete neuronal cell types in multiple hypothalamic areas allows the brain to balance the activity of anabolic and catabolic neurocircuits in order to maintain energy homeostasis.

Integration of Adiposity and Satiety Signals

In comparison to our rapidly increasing understanding of hypothalamic neurocircuits involved in energy homeostasis, relatively less is known about how changes in energy intake are adjusted to meet changing energy needs on a meal-to-meal basis. Since food in general is consumed in discrete bouts or meals, hypothalamic mechanisms involved in energy homeostasis must ultimately impinge upon systems responsible for initiation and/or termination of individual meals. Indeed, recent evidence suggests that long-term adiposity signals are integrated with input from short-term, meal-related signals to influence meal size, and that changes of meal size are a key mechanism for adaptive changes of food intake in the service of energy homeostasis (Figure 4).

Cholecystokinin

Cholecystokinin (CCK) is a gut-derived peptide that is released from I-cells following nutrient entry into the duodenum, and it induces satiety by activating vagal afferent fibers that terminate in the NTS. In addition to promoting the termination of a meal, CCK also slows gastric emptying, reduces gastric acid secretion and promotes contraction of the gall bladder. Although exogenous CCK reliably reduces the size of individual meals, repeated CCK administration does not effectively lower body weight. This is because as weight is lost and plasma levels of insulin and leptin decline, an increase in the number of meals occurs that negates the effect of CCK to reduce meal size. This

Figure 3 Hypothalamic neurocircuits involved in energy homeostasis.

Figure 4 Integration of adiposity signals and satiety signals.

finding highlights the inherently limited potential of meal-related satiety peptides to promote therapeutic weight loss.

Several lines of evidence suggest that leptin reduces food intake, at least in part, by increasing sensitivity to meal-related signals such as CCK. Leptin-mediated food intake suppression is characterized by reduced meal size and exogenous leptin potentiates the satiety effect of CCK. Conversely, in conditions of reduced or deficient leptin signaling, increased energy intake is due, in part, to an increase in meal size associated with reduced sensitivity to satiety signals. Therefore, if an individual goes on a calorically restricted diet and loses weight, the decline in circulating levels of both insulin and leptin ultimately reduces sensitivity to endogenous satiety signals such as CCK. Consequently, the amount of food consumed during each meal tends to increase, amounting to a major contributor to positive energy balance and recovery of lost weight. In addition to CCK, there are a host of other meal-related signals released from the gastrointestinal tract, several of which are already known to interact with adiposity signals including glucagon-like peptide-1 (GLP-1) and amylin.

Ghrelin

Whereas CCK and other meal-related peptides promote meal termination, the gastric hormone ghrelin, stimulates feeding. Plasma ghrelin levels are increased with fasting and fall rapidly following a meal. Moreover, exogenous administration of ghrelin when given systemically or centrally stimulates feeding and activates NPY/AgRP neurons in the ARC. Thus, during weight loss, elevated plasma ghrelin levels, in combination with reduced insulin and leptin signaling, contribute to the regain of lost weight. One caveat to this widely accepted model of ghrelin biology is that for biological activity, ghrelin must be acylated (specifically, it is octanoylated), and deacylation occurs rapidly in plasma, such that most immunoreactive ghrelin in circulation may be devoid of bioactivity. Whether circulating, biologically active ghrelin is affected by changes in

energy balance, and whether such changes play a vital role in energy homeostasis, await further study.

Summary

In conclusion, afferent input from adiposity signals, such as insulin and leptin, convey information regarding long-term energy stores to key brain areas that integrate this input with information regarding short-term energy availability from nutrient-related signals. Thus, when the brain perceives that both short- and long-term energy needs are met, anabolic neurocircuits that stimulate food intake and reduce energy expenditure are inhibited, whereas catabolic pathways that limit food intake and increase energy expenditure are activated so as to maintain energy homeostasis. Adaptive changes in the activity of this reciprocally regulated, opposing, dual-effector control system lie at the core of the energy homeostasis system.

Glossary

Metabolic compartmentation Segregation of intermediates and enzymes of a metabolic pathway by membranes, binding to a specific surface or direct interaction in protein complexes allowing metabolite channeling.

Metabolite channeling Local transfer of metabolic intermediates between sequential enzymes or transport reactions without equilibration with bulk solution.

Microcompartment Structural unit allowing metabolic compartmentation, also called metabolon.

Mitochondrial contact sites Close adhesions of inner and outer mitochondrial membrane that can be observed by electron microscopy and can be isolated as a

separate microcompartment. Contact sites consist of multilipid/protein complexes with variable composition and are involved in energy transduction (e.g., containing adenylate translocator (ANT)/voltage-dependent anion channel (VDAC) or ANT/mitochondrial creatine kinase (MtCK)/VDAC) or in protein import.

Mitochondrial permeability transition

pore A multienzyme complex, probably composed of VDAC, ANT, Bax, cyclophilin, MtCK, and others, that is crucially involved in early events that trigger apoptosis-like release of cytochrome *c* and other apoptosis-inducing factors into the cytosol.

Subcellular microcompartments, consisting of multienzyme complexes embedded within the cellular, highly viscous matrix, associated with the cytoskeleton, or situated along membranes, are operating according to exclusion principles and favor preferred pathways of intermediates. This process, called metabolite or substrate channeling, is defined as transfer of intermediates between sequential enzymes without equilibration of these metabolites with the surrounding bulk solution. Such an association between two or more sequential enzyme or transport reactions in a microcompartment, forming a distinct functional pool of intermediates, is also called functional coupling. It can be considered as a general mechanism to increase efficiency of sequential reactions in a metabolic pathway. As metabolite channeling leads to segregation of a metabolic pathway from other cellular reactions, it represents a specific kind of metabolic compartmentation similar to that operating within membrane-separated organelles or by restricted two-dimensional diffusion at surface boundary layers. Here, metabolite channeling is described with special emphasis on high-energy phosphate channeling by creatine kinase (CK), the phosphocreatine circuit or shuttle, and the mitochondrial CK (MtCK) isoenzyme.

Subcellular Microcompartments and Mechanisms of Metabolite Channeling

Life most likely originated autotrophically *de novo* in metabolic complexes organized on FeS₂ (pyrite) mineral surfaces, the earliest form of microcompartments. Likewise, a cell is by no means represented best by a well-mixed bag of enzymes, behaving in complete equilibrium according to solution kinetics. Because of the intricate structural and functional organization of living cells, enzymes and metabolites do not behave as if they were freely diffusible in solution. Instead, they may form

structurally, functionally, and temporally defined subcellular microcompartments, either via strong static or via fickle, dynamic interactions with other enzymes, proteins, or subcellular structures. Such a structural organization of pathway components is a general prerequisite for metabolite channeling. It may involve (1) huge covalently linked enzyme complexes (or multifunctional enzymes) such as fatty acid synthase (FAS), (2) kinetically stable multienzyme complexes such as pyruvate dehydrogenase (PDH) or bacterial and plant tryptophan synthase (TS), (3) more dynamic, reversibly associating enzymes such as glycolytic complexes containing glyceraldehyde phosphate dehydrogenase (GAPDH) or glycerol phosphate dehydrogenase (GPDH), or (4) colocalization on subcellular particles or biological membranes. These associations allow the transfer of intermediates between the channeling components by different mechanisms: (1) physical hindrance or electrostatic effects prevent mixing with bulk solution and drive a directed diffusion (e.g., TS and FAS), (2) sequential covalent binding to very close active sites in the reaction sequence (e.g., PDH), (3) transfer of noncovalently bound intermediates between active sites (e.g., nicotinamide adenine dinucleotide dehydrogenase), and (4) transfer in dynamic multienzyme complexes (GAPDH and GPDH) or in an unstirred membrane surface layer (MtCK). These mechanisms can be fulfilled in both, static and dynamic enzyme associations. However, although static associations allow for an almost perfect or tight channeling of metabolites, dynamic channeling is often only partial or leaky.

Advantages of Metabolite Channeling

Sequestering of intermediates in a microcompartment through channeling provides kinetic and regulatory advantages not only for the reaction sequence itself (see [Figure 1](#)) but also for cellular metabolism. In general: (1) enzyme reaction rates

Figure 1 Free diffusion vs. metabolite channeling. Compartmentation of a reaction sequence without equilibration with bulk solution leads to shorter transition times and further advantages (see text).

and equilibria are controlled by local and enzyme-bound substrates, rather than bulk-phase substrate concentrations; (2) for a readily reversible reaction, local supply of substrate and removal of product may drive the reaction in the desired direction; (3) sequestered intermediates are present at high local concentrations and an apparently low K_m for these intermediates can be observed with the channeling complex compared to the nonchanneling situation measured with isolated components; (4) metabolites are isolated from competing reactions, for example, between anabolic and catabolic pathways; (5) the lifetime of the intermediate in the solvent phase is shortened relative to free diffusion, which may be essential in the case of unstable intermediates; (6) in certain cases, the unfavorable energetics of desolvating the substrate that precedes binding to the enzyme is avoided; (7) channeling components can be regulated by modulators that affect enzyme associations; and (8) a larger degree of metabolic control of the overall flux of the reactions can be achieved, for example, via feedback regulatory mechanisms such as substrate activation, product inhibition, and cooperativity.

Subcellular Targeting of Glycolytic Multienzyme Complexes

In muscle, glycolytic enzymes are targeted to the actin-containing thin filaments at the sarcomeric I-band region where they form highly complex metabolons. The I-band in *Drosophila* flight muscle contains a multienzyme complex consisting of GDPH-1, aldolase, and GAPDH. By elegant experiments with transgenic *Drosophila* expressing GDPH-3 instead of GDPH-1, it could be shown that all three glycolytic enzymes no longer colocalize in the I-band to form a microcompartment. Even though the full complement of active glycolytic enzymes was still present, their failure to colocalize in the sarcomer resulted in the inability to fly. Thus, correct targeting and formation of multienzyme complexes that lead to functionally coupled microcompartments and substrate/product channeling seem to be a prerequisite for proper function of glycolysis and ultimately for correct muscle function. In mammalian cells, CK is also participating in the glycolytic metabolon.

More recently, metabolomic studies have envisaged a comprehensive analysis of cellular metabolites, their changes in time, as well as the modeling of these processes. Such systems biology approaches have the potential to reveal many more cases of dynamic and time-resolved metabolite-channeling events within the cellular metabolic network.

Compartmentation of CK Isoenzymes and Channeling of High-Energy Phosphates

The CK/Phosphocreatine Circuit or Shuttle

One fundamental requirement of life is energy supply. Cellular energy demand and supply are balanced, and tightly regulated for economy and efficiency of energy use. CK is a major enzyme of higher eukaryotes that copes with high and fluctuating energy demands to maintain cellular-energy homeostasis, in general, and to guarantee stable, locally buffered adenosine triphosphate (ATP)/adenosine diphosphate (ADP) ratios, in particular.

The enzyme catalyzes the reversible phosphoryl transfer from ATP to creatine (Cr) to generate ADP and phosphocreatine (PCr). Thus, CK is able to conserve energy in the form of metabolically inert PCr and vice versa, to use PCr to replenish global as well as local cellular ATP pools. As PCr can accumulate to much higher cellular concentrations than ATP, the CK/PCr system constitutes an efficient and immediately available cellular energy buffer. In addition, tissue-specific CK isoenzymes are located in the cytosol (dimeric muscle-type MM-CK and brain-type BB-CK) and within the mitochondrial intermembrane space (sarcomeric MtCK and ubiquitous MtCK, both forming octamers and dimers). CK isoenzymes are often associated with sites of ATP supply, where they generate PCr, or with sites of ATP consumption, where they regenerate ATP by using PCr. Thus, together with the faster diffusion rate of PCr as compared to ATP, the CK/PCr system also supports an intrinsic energy-transfer system (CK/PCr circuit or shuttle), coupling sites of energy generation (oxidative phosphorylation or glycolysis) with sites of energy consumption (Figure 2). This circuit is particularly important in large and/or polar cells, such as spermatozoa where diffusional limitations of adenine nucleotides, especially ADP, along the sperm tail become especially apparent.

Channeling with Cytosolic CK

Cytosolic CK is only partially soluble. A significant fraction is structurally and functionally associated or colocalized with different, structurally bound ATPases or ATP-regulated processes. These include (1) different ion pumps in the plasma membrane, (2) the sarcomeric M-band of the myofibrils in muscle, (3) the calcium pump of the muscular sarcoplasmic reticulum, and (4) the ATP-gated K^+ -channel. In all these cases, PCr is used for the local regeneration of ATP, which is directly channeled from CK to the ATP-consuming ATPase without major dilution by the surrounding bulk solution. Only in some cases, the physical basis for the metabolite channeling is known. For example, MM-CK uses a charge clamp consisting of four lysine residues to specifically bind to partner molecules, myomesin and M-protein in the M-band. This allows for an isoenzyme-specific association of MM-CK with the sarcomeric M-band of the myofibrillar apparatus. There, MM-CK is ideally positioned in the middle of the acto-myosin overlap zones, situated symmetrically on both sides of the M-band, to regenerate *in situ* the ATP that is hydrolyzed during muscle contraction.

Cytosolic CK is structurally associated with the key regulatory enzyme of glycolysis, phosphofructokinase, which itself

Figure 2 The creatine kinase (CK)/phosphocreatine (PCr) system. Isoenzymes of CK (blue) are found in different compartments such as mitochondria (octameric MtCK, (a)) and cytosol (dimeric CK, (b)–(d)) in soluble form (c) or associated to a different degree to ATP-delivering ((a) and (b)) or -consuming processes (d). A large cytosolic PCr pool up to 30 mM is built up by CK using ATP from oxidative phosphorylation like in heart (a) or glycolysis like in fast-twitch glycolytic muscle (b). PCr is then used to buffer global (c) and local (d) ATP/ADP ratios. In cells that are polarized and/or have very high or localized ATP consumption, these CK isoenzymes, together with easily diffusible PCr, also maintain an energy shuttle between ATP-providing or -consuming processes ((a) and (d)). Metabolite channeling occurs where CK is associated with ATP-providing or -consuming transporters, pumps, or enzymes ((a), (b), and (d)). Creatine (Cr) is synthesized in only few cell types (e.g., liver and kidney) and has to be taken up from the blood stream by a specific Cr transporter (CRT) that is highly expressed by Cr-containing target cells.

is regulated by ATP. Likewise, structural and functional interactions of cytosolic CK with the PAR-1 receptor of the thrombin-signaling pathway and with the ATP-gated K^+ -channel, respectively, have been demonstrated. A tight functional coupling of CK to ATPases, for example, actomyosin ATPase and ion pumps, such as the K^+ /Na $^+$ -ATPase or the Ca $^{2+}$ -ATPase, has the advantage (1) that product inhibition of the ATPase by ADP and H $^+$ is avoided, because the latter are both substrates of the CK reaction ($PCr + ADP + H^+ \leftrightarrow Cr + ATP$) and (2) that the high free energy of ATP hydrolysis (ΔG_{ATP}) at sites of ATP hydrolysis is preserved by keeping locally very high ATP/ADP ratios due to coupling of CK with those ATPases *in situ* and, thus, preventing energy dissipation that would otherwise be caused by transport of ATP and mixing it with the bulk surrounding. Interestingly, the strongest phenotype of CK double knockout mice, which no longer express cytosolic MM-CK and mitochondrial MtCK in muscle, is characterized by significant difficulties with intracellular calcium handling and muscle relaxation, emphasizing the physiological importance of the CK system for the energetics of intracellular calcium homeostasis, in general, and the delivery of ATP to the energetically demanding Ca $^{2+}$ -ATPase, in particular.

Channeling in Energy-Transducing Mitochondrial Microcompartments

MtCK forms mainly large, cuboidal octamers (Figure 3) that are present (1) between the outer and inner mitochondrial membrane (the so-called intermembrane space of

mitochondria) and preferentially localized at the so-called mitochondrial contact sites between outer and inner mitochondrial membrane, as well as (2) in the cristae space (see Figure 3 inset). The kinase catalyzes the direct transphosphorylation of intramitochondrial-produced ATP and Cr from the cytosol into ADP and PCr. ADP then enters the matrix space to stimulate oxidative phosphorylation, giving rise to mitochondrial recycling of a specific pool of ATP and ADP, while PCr is the primary high-energy phosphoryl compound that leaves mitochondria into the cytosol. The molecular basis for such directed metabolite flux is channeling between the large, cuboidal MtCK octamer and two transmembrane proteins, adenylate translocator (ANT) and mitochondrial porin or voltage-dependent anion channel (VDAC). ANT is an obligatory antiporter for ATP/ADP exchange across the inner mitochondrial membrane, while VDAC is a nonspecific, potential-dependent pore in the outer mitochondrial membrane. The MtCK-linked metabolite channeling is based on (1) colocalization, (2) direct interactions, and (3) diffusion barriers. MtCK tightly binds to cardiolipin, an acidic phospholipid that is specific for the mitochondrial inner membrane. As ANT molecules are situated in a cardiolipin patches, this leads to colocalization and metabolite channeling between both proteins, MtCK and ANT, in the cristae as well as in the intermembrane space (Figure 3). MtCK in the intermembrane space further interacts with outer membrane phospholipids and VDAC, thus virtually cross-linking inner and outer membrane and contributing to the mitochondrial contact sites. Increasing the external calcium concentrations strengthens the interaction of MtCK with VDAC, which may improve channeling under cytosolic calcium overload as occurring at

Figure 3 (Inset) Dual localization of mitochondrial CK by electron microscopy. Post-embedding immuno-gold labeling of MtCK in a mitochondrion from photoreceptor cells of chicken retina, showing localization of MtCK in the peripheral intermembrane space (arrows) and along the cristae membranes. Scheme: microcompartments and metabolite channeling of mitochondrial CK. After the import of nascent MtCK over the mitochondrial outer membrane and cleavage of the targeting sequence, MtCK first assembles into dimers. Dimers rapidly associate into octamers (top left), and although this reaction is reversible, octamer formation is strongly favored by high MtCK concentrations and MtCK binding to acidic phospholipids. MtCK is then found in two locations: (1) in the so-called mitochondrial contact sites associated with ANT and VDAC (top center) and (2) in the cristae associated with ANT only (at right). In contact sites, MtCK simultaneously binds to inner and outer membrane due to the identical top and bottom faces of the octamer. Binding partner in the inner membrane is the twofold negatively charged cardiolipin, which allows a functional interaction with ANT. This carrier is situated in cardiolipin membrane patches that can be induced by MtCK itself. In the outer membrane, MtCK interacts with other acidic phospholipids and, in a calcium-dependent manner, directly with VDAC. Substrate and product fluxes between MtCK and the associated proteins are depicted as arrows. In contact sites, this substrate channeling allows for a constant supply of substrates and removal of products at the active sites of MtCK. In cristae, only ATP/ADP exchange is facilitated through direct channeling to the MtCK active site, while Cr and PCr have to diffuse along the cristae space to reach VDAC. Further channeling may take place within mitochondrial supercomplexes that include carriers, ATPase and respiratory chain complexes (lower part). The active ATP/ADP exchange maintained by coupled MtCK favors ATP generation by the F₀F₁-ATPases and, thus, proper functioning of the respiratory chain, which could otherwise generate elevated levels of superoxide and reactive oxygen species (ROS).

low-cellular-energy state. Some studies suggest that only the membrane-bound, octameric form of MtCK is able to maintain the metabolite channeling described above. Finally, the limited permeability of VDAC and, thus, of the entire outer membrane creates a dynamic microcompartmentation of metabolites in the intermembrane space that contributes to MtCK-linked channeling and separate mitochondrial ATP and ADP pools. Similar to MtCK, hexokinase is able to use intramitochondrially produced ATP by binding to VDAC from the cytosolic mitochondrial surface at contact sites containing only ANT and VDAC. The direct functional coupling

of MtCK to oxidative phosphorylation can be demonstrated with oxygraph respirometry on skinned muscle fibers from normal and transgenic mice lacking MtCK. Although in normal muscle fibers Cr stimulates mitochondrial respiration, this phenomenon is missing in fibers of MtCK knockout mice.

By favoring ATP/ADP exchange through ANT in the mitochondrial inner membrane, cytosolic Cr and the MtCK reaction not only stimulate the rate of mitochondrial respiration, but also lead to improved coupling between respiration, ATP synthesis, and mitochondrial energy channeling, which finally reduces formation of potentially deleterious reactive

oxygen species (ROS; [Figure 3](#), lower part). Both effects of MtCK-related metabolite channeling, stimulation of mitochondrial respiration and lowering of ROS production, may contribute to the remarkable cell- and specifically neuroprotective action of Cr supplementation *in vitro* and *in vivo*. This is an instructive example of how efficient, multiple metabolite channeling events can be beneficial for human health.

Oxidative damage of MtCK, induced by reactive oxygen and nitrogen species, generated under cellular stress situations, for example, in infarcted heart or under chemotherapeutic intervention by anthracyclines, leads to inactivation and dimerization of MtCK, as well as to dissociation of the enzyme from the mitochondrial inner membrane. Thus, important prerequisites for efficient channeling of high-energy phosphates by MtCK are negatively affected. These events contribute to cardiac energy failure and specific anthracycline cardiotoxicity.

Mt CK, Intramitochondrial Inclusions, and Low-Cellular-Energy State

MtCK is an indicator for cellular low-energy stress, that is, the expression of this enzyme is highly upregulated in patients with mitochondrial myopathies in the so-called ragged-red

Figure 4 Intramitochondrial inclusions in patients with mitochondrial myopathies consist of mitochondrial MtCK. Immunoelectron histochemistry of human intramitochondrial crystalline ‘railway-track’ inclusions seen in patients with mitochondrial myopathies showing ‘ragged-red’ skeletal fibers as a hallmark of the disease. Note the grossly enlarged mitochondrion, here from a patient with Kearns–Sayre syndrome, displaying the typical regularly spaced intracristae inclusions (dark) surrounded by mitochondrial inner cristae membranes. The section has been stained by rabbit anti-MtCK antibodies, followed by colloidal gold-conjugated second antibody (in collaboration with Dr. AM Stadhouders, Nijmegen, The Netherlands). Note that the dark inclusion bodies are heavily and specifically stained by the small 10-nm gold particles, indicating a high propensity of MtCK at these locations. Isolation of such inclusions plus image processing of sections through them revealed that they consist mainly of crystalline MtCK octamers, which crystallize in sheet-like structures. Modified from Stadhouders AM, Jap PHK, Winkler H-P, Eppenberger HM, and Wallimann T (1994) Mitochondrial creatine kinase: A major constituent of pathological inclusions seen in mitochondrial myopathies. *Proceedings of the National Academy of Sciences of the United States of America* 91(11): 5089–5093.

skeletal muscle fibers, where mitochondrial volume and size are markedly increased and where characteristic intramitochondrial railway-track inclusions are observed as a hallmark of pathology. The latter were shown to consist of crystalline sheets of MtCK (see [Figure 4](#)). Similar MtCK inclusions can also be induced in animals by chronic Cr depletion, leading to cellular low-energy state. Even more generally, cellular low-energy stress, be it induced by chronic endurance training, fasting, Cr depletion, or pathologies in ATP generation, such as mitochondrial dysfunction seen in patients with mitochondrial cytopathies, induces a coordinated induction of energy gene expression to compensate for impaired energy supply and transport. In the case of MtCK, one of the most prominent among these genes, overexpression is such that it leads to crystallization of the enzyme in a pathological state as described above.

Mt CK and the Mitochondrial Permeability Transition Pore

MtCK, together with its substrate Cr, has been implicated in regulation of the mitochondrial permeability transition pore that is crucially involved in triggering apoptosis. This seems to be due to metabolite channeling in the MtCK/ANT microcompartment also, which maintains high ADP concentrations in the matrix space that are inhibitory for permeability transition. Thus, the CK system and its substrates seem to exert additional effects that are not necessarily directly coupled to improving cellular energetics. This may explain the remarkable cell- and neuroprotective effects of Cr supplementation that have been reported.

Metalloproteases

D S Auld, Harvard Medical School, Boston, MA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Aminopeptidase Protease catalyzing the cleavage of amino acids from the N terminus of polypeptides.

Carboxypeptidase Protease catalyzing the cleavage of amino acids from the C terminus of polypeptides.

Dipeptidyl peptidase Protease that removes two amino acids at a time from the N or C terminus of the polypeptide.

Endoprotease Protease that acts internally on a polypeptide chain.

Protease or proteinase Enzyme catalyzing the hydrolysis of peptide bonds in proteins.

Metalloproteases are a class of enzymes that use protein-bound metal ion(s) and a coordinated water molecule to catalyze the addition of water to a peptide bond. Proteases are necessary for the survival of all living creatures, and are encoded by ~2% of the genes in all kinds of organisms. They are an exceptionally important group of enzymes in biology, medical research, and biotechnology.

Functional Classification

Scientists who work in the general area of proteolytic enzymes have given much latitude to the naming of such enzymes. At present, they are frequently referred to as proteases, proteinases, and peptidases, in an interchangeable manner. Some of the terms used are more illustrative of their function. Exopeptidases cleave one or a few amino acids from the N or C terminus of a polypeptide, whereas endoproteases act internally on the polypeptide chain. Aminopeptidases and carboxypeptidases act on the N and C terminus of the polypeptide, respectively, usually cleaving off one amino acid at a time, but some are capable of removing two (dipeptidyl peptidases) or three (tripeptidyl peptidases) amino acids at a time. These enzymes are often classified according to their general mechanism type as structural/functional information becomes available. This classification results in four major types: aspartic, cysteine, metallo-, and serine, each named for a critical component of the active site. In the case of metalloproteases, the metal that is most frequently found is zinc. However, manganese, cobalt, and iron are also observed for some specific cases. Proteases are often named according to a specific physiological substrate that they hydrolyze. Angiotensin I converting enzyme (ACE I) is a zinc metalloprotease that cleaves the C-terminal dipeptide from angiotensin I to produce the potent vasopressor, octapeptide, angiotensin II and inactivates bradykinin by the sequential removal of two dipeptides from its C terminus. The role of this enzyme in blood pressure control and water and salt metabolism was identified through the use of potent inhibitors of its action. It is also defined as a zinc dipeptidyl carboxypeptidase. Tumor necrosis factor- α (TNF- α) is a cytokine that induces protective inflammatory reactions and kills tumor cells. Soluble TNF- α is released from its membrane-bound precursor by a membrane-anchored proteinase, identified as a multidomain metalloproteinase

called TNF- α -converting enzyme (TACE). This enzyme is also named as a disintegrin-like and metalloproteinase site (ADAMS) 17 endopeptidase for a classification based on structural considerations. Frequently, such a substrate-based classification requires a very general term when the substrate specificity is only known in general terms, such as matrix metalloproteinase (MMP).

Structural Classification

During the past decade, the advent of sequencing the protein through its gene and the ability to obtain three-dimensional (3D) structures on proteins allowed the recognition of metalloprotease families. These studies permit several different classifications based, for example, on the type of metal site present and/or similarity in overall protein fold and/or amino acid sequence similarities.

Metal Sites

The metal that is found in most metalloproteases is zinc. The function of these enzymes is therefore related to the chemistry of zinc, which is quite versatile. It has a remarkably adaptable coordination sphere that allows it to accommodate a broad range of coordination numbers and geometries when forming complexes. If the zinc retains a positive charge after ligating to protein side chains, it can act as a Lewis acid in catalysis. If a zinc-bound water is converted to hydroxide, the zinc site can act as a base or nucleophile in catalysis. In this sense, the catalytic zinc sites are amphoteric. The oxidation/reduction properties of its neighboring transition metals are a major cause of their ligand exchange rates, amphoteric properties, and coordination geometries. As zinc has a filled *d*-shell, it does not have oxidation/reduction properties, thus providing a stable metal ion species in a biological medium whose redox potential is in constant flux. There are now about six dozen X-ray diffraction and nuclear magnetic resonance (NMR) structures of individual metalloproteases. These structures provide standards of reference for the identity and nature of zinc ligands in other proteins, for which only the primary structure is known, and thus allow the formation of metalloprotease families. Three types of distinct zinc-binding motifs emerge

Figure 1 Zinc-binding sites in metalloproteases. Schematic shown is for a 'catalytic' site, represented by carboxypeptidase A, the 'structural' site for the matrix metalloproteases, and the 'cocatalytic' site of *Aeromonas* aminopeptidase.

from these analyses: 'catalytic', 'cocatalytic', and 'structural' sites (Figure 1). In zinc metalloenzymes, the most common amino acids that supply ligands to these sites are His, Glu, Asp, and Cys. Thus far, Cys has been found as a ligand in only one metalloprotease.

Catalytic Sites

3D structures of the catalytic sites of about five dozen metalloproteases show that zinc forms complexes with any three nitrogen (His) and oxygen (Glu or Asp) donors, with His being the predominant amino acid chosen by a ratio of ~2:1 over Glu plus Asp. Histidine (usually the N ϵ 2 nitrogen) may be chosen because of its capacity to disperse charge through H-bonding of its nonligating nitrogen. The carboxylate anion of Glu and Asp ligands will reduce the charge on the metal, making it more difficult for the metal-bound water to ionize and for the metal to act as a Lewis acid catalyst. The first two metal ligands are separated by a short amino acid spacer with the third ligand being supplied by a longer spacer. In catalytic zinc sites of proteases, the ligands are generally supplied from within an α -helix or a β -sheet that places restraints on the coordination of the metal by the side chains of the amino acids. The overall length of such sites can be as small as 11 amino acids, as is observed in the astacin super family of zinc proteases.

Catalytic zinc sites are usually four or five coordinates in metalloproteases and the geometry in the free state is frequently distorted tetrahedral or trigonal bipyramidal. Water is always a ligand to these sites. In principle, the zinc and its bound water molecule can be involved in catalysis by a number of different means (Figure 2). Metalloproteases generally have a Glu or His residue within H-bonding distance of the zinc-bound water that could play the role of a general acid/base catalyst or may stabilize the transition state of a tetrahedral intermediate. Alternatively, the direct ionization of the metal-bound water can lead to nucleophilic catalysis by zinc hydroxide, while displacement of water

Figure 2 The role of the metal and bound water in catalysis. The water can ionize either (1) without or (2) with the help of the adjacent base supplied by an amino acid residue. The zinc-bound water can also (3) be displaced by substrate or (4) the coordination sphere be expanded upon interaction with substrate.

or expansion of the coordination sphere can result in Lewis acid catalysis by the catalytic zinc atom. The three protein ligands, their spacing, and secondary interactions with neighboring amino acids, in conjunction with the vicinal properties of the active center created by protein folding, are all critical to the mechanisms through which zinc is involved in catalysis.

Structural Sites

Metalloproteases frequently use either disulfides or calcium ions to aid in stabilizing the structure of the enzyme. Structural metal sites have four protein ligands and no metal-bound water molecule. Cys ligands, followed by His, are the preferred ligands in such sites in zinc metalloenzymes. However, only one Cys-containing zinc site is observed in the class of metalloproteases. Human picornavirus endoprotease 2A binds one zinc to three Cys and one His in the sequence Cx₁Cx₅₇Hx₁C. One other metal site that fits the criteria for a structural zinc site has been observed in the matrix metalloproteases and has a signature of Hx₁Dx₁₂Hx₁₂H (Figure 1). This site may indirectly affect the activity of the enzyme. The amino acids adjacent to the third and fourth His ligands to the structural zinc site provide a number of hydrophobic residues that border a catalytic Glu residue. These residues could provide a hydrophobic environment for the Glu carboxylate group and thus raise its pK_a and allow it to play a role in stabilizing the transition state in catalysis. The zymogen form of the MMPs has a Cys ligand in place of the zinc-bound water in the catalytic zinc site, thus having the properties of a structural zinc site.

Cocatalytic Sites

These sites in metalloenzymes contain two or three metals in close proximity with two of the metals bridged by a side-chain moiety of a single amino acid residue, such as Asp,

Glu, His, or a carboxylated lysine, LysCO, and sometimes a water/hydroxide molecule (Figure 1). Thus far, structures for amino-, carboxy-, and a tripeptidase have been reported. Asp and Glu and, sometimes, an additional water molecule are the preferred bridging ligands for these sites. The distance between the metals is dictated by the type of bridging ligand, 2.8–3.6 Å, for the carboxylate. No Cys ligands have been reported for these sites.

The bridging amino acids and H₂O could have critical roles in catalysis. Thus, their dissociation from either or both metal atoms during catalysis could change the charge on the metal promoting its action as a Lewis acid or allowing interaction with an electronegative atom of the substrate. Alternatively, the bridging ligand might participate transiently in the reaction as a nucleophile or general acid/base catalyst. In this manner, the metal atoms and their associated ligands would play specific roles in each step of the reaction that works in concert to bring about catalysis.

The ligands to these sites often come from nearly the entire length of the protein. The metals may therefore be important to the overall fold and stability of the protein as well as catalytic function. The secondary structural elements, α -helices and β -sheets, again play a strong role in supplying the ligands. However, in contrast to the catalytic zinc sites, the ligands often reside one or two amino acids from the N or C terminus of an α -helix or a β -sheet. These positions should allow more flexibility in forming the cocatalytic site.

Some of the cocatalytic sites contain metal ions other than zinc ions. The *Escherichia coli* methionine aminopeptidase-1, MetAP-1, the hyperthermophile *Pyrococcus furiosus* methionine aminopeptidase-2, and human methionine aminopeptidase-2 have been isolated as dicobalt enzymes and the *E. coli* proline aminopeptidase as the dimanganese enzyme. The physiological metal for these enzymes is still not certain. Zinc works as well as cobalt in the yeast aminopeptidase-1, and recent studies of the *E. coli* MetAP-1 indicate that it functions as an Fe(II) enzyme.

Genetic Origin and Ligand Nature

The identification of the ligands to these metal sites and the spacing characteristics in combination with modern sequencing techniques have led to further classifications of the metalloproteases. An excellent source of information on proteolytic enzymes is the *Handbook of Proteolytic Enzymes* and its associated website of MEROPS. This protease database groups peptidases into three levels – clans, families, and an individual peptidase. A clan contains all the peptidases that are believed to have diverged from a single evolutionary origin. In terms of the metalloproteases, they may have similar catalytic metal sites and overall folds. The clans can be further divided into families of proteases that show significant similarities in amino acid sequence. Finally, a member of a family is an individual peptidase. The Release 9.3 (December, 2010) of MEROPS gives information on 60 846 sequences of metallopeptidases and groups them into 21 clans, 58 families, and 724 identified metallopeptidases with links to 165 3D structures.

Physiological Function

These enzymes are important to a wide range of physiological processes that are too numerous to cover completely herein. Carboxypeptidase A (CPD A), was the first zinc protease and second zinc enzyme discovered. The zinc exopeptidases, CPD A and B, compliment the action of the serine endopeptases, trypsin, and pepsin, in the degradation of food proteins. The serine proteases cleave proteins internally either at positions of basic amino acids such as Lys or Arg (trypsin) or in hydrophobic aromatic amino acids such as Phe or Trp (pepsin). The zinc exopeptidases then liberate the essential amino acids Lys and Phe from the C terminus of the peptides generated by the endopeptases. The combination of structural and functional studies on these metalloproteases has revealed the presence of other members of this family that are important to hormone processing, immune/inflammatory activity, and blood-clotting functions. Information on the active sites of CPD A led to the development of specific inhibitors of ACE decades before a crystal structure was known for it, based on the proposition that both enzymes contained a zinc-bound water. Drugs for control of hypertensin were identified by these means. Methionyl aminopeptidases, MetAP, remove the N-terminal methionine residue from newly transcribed polypeptides. The physiological importance of these enzymes is underscored by the lethal nature of the removal of the MetAP gene from a number of bacterial sources. The *Handbook of Proteolytic Enzymes* along with its associated MEROPS website is an excellent source for detailed information on metalloproteases.

Metalloprotease Inhibition

The crucial nature of these enzymes to physiological processes has led to considerable research efforts on discovering their natural inhibitors that could be involved in their regulation. The MEROPS website contains a good compilation of such inhibitors. The importance of the metal and its bound water is the key to inhibiting the metalloproteases (Figure 3). Inhibition can be accomplished by one of the three ways: (1) displace the water by an inhibitor binding to the metal,

Figure 3 Inhibition of zinc proteases is accomplished by either (1) removing the water, (2) removing the metal, or (3) binding a metal hydroxide complex.

(2) remove the metal, or (3) bind a metal hydroxide complex to the catalytic metal and an active site residue.

Displacement of the Metal-Bound Water

The importance of zinc proteases in both normal and pathological processes makes them targets for drug design. The fact that zinc can readily form four-, five-, and six-coordinate complexes has led to the design of a number of synthetic inhibitors that act by displacing the metal-bound water. These studies have shown that the strength of the chelator–metal interaction increases the potency of the agent as a drug. The inhibitors are designed to have both structural specificity for the active site and a war head that will bind to the catalytic metal. Specificity is incorporated on either side of the metal-binding ligand. Popular warheads are hydroxamates, thiolates, and phosphoryl groups as chelating ligands. Carboxyalkyl and phosphinic acid groups are used as transition state or tetrahedral intermediate mimics.

Catalytic Chelators

It should also be possible to inhibit zinc proteases by removing the metal. This is often not very specific and many common chelators, such as ethylenediamine tetra-acetic acid (EDTA), are ineffective. However, D-penicillamine, a drug used to treat Wilson's disease and rheumatoid arthritis, has been shown to catalyze the release of zinc from CPD A. In the presence of a second scavenger chelator, such as EDTA or the physiological chelator, thionein (apo-metallothionein), the inhibition is quite potent. From a physiological perspective, such a mechanism of inhibition would be essentially irreversible, given the low levels of free zinc believed to be present in the body.

Inhibition by Metal Hydroxide Complexes

Many zinc proteases are inhibited by adding zinc to the assays. In the case of the exopeptidase, CPD A, and the endoprotease, thermolysin, a combination of kinetic and structural studies have shown this inhibition is due to zinc hydroxide binding the ionized carboxylate of an active site glutamate residue

which then bridges to the catalytic zinc by displacing its bound water. In the case of CPD A, both zinc and lead inhibit in the form of $M(OH)Cl$ with submicromolar-inhibition constants. If multidentate ligands interact with the inhibitory metal and the enzyme-active site, significantly stronger inhibition is anticipated. Inhibition by such metal hydroxide complexes could be important to regulatory and/or toxicological processes of zinc proteases.

Glossary

α_2 -Macroglobulin A glycoprotein in blood of 720 kDa consisting of four identical subunits. It inhibits most endopeptidases regardless of their catalytic mechanism by physical entrapment of the enzyme molecule upon proteolytic attack on the macroglobulin.

ADAM Abbreviation for type I transmembrane proteins with a disintegrin and metalloprotease domain, some of which are involved in shedding of cell-surface molecules and have some overlapping properties shared with MMPs. While the primary structures of the metalloprotease domain are homologous to each other, about half of the members of this family do not contain the strictly conserved zinc-ion-binding motif, and are probably proteolytically inactive.

ADAMTS Abbreviation for proteins with a disintegrin and metalloprotease domain with type I thrombospondin motifs. The metalloproteinase domains are homologous to ADAMs, but they do not possess a transmembrane domain.

Extracellular matrix A complex network of secreted extracellular macromolecules (e.g., collagens,

proteoglycans, glycoproteins, fibronectin, and complex carbohydrates) which provides an organized lattice and helps to hold cells and tissues together in multicellular organisms.

Metzincin Metalloproteinases that contain the zinc-ion-binding motif HEXXHXXGXXH and a conserved methionine that forms a unique Met-turn structure, e.g., matrix metalloproteinases, astacins, repolysins, ADAMs, ADAMTSs, pappalysins, serralsins, and leishmanolysin.

MMP Abbreviation for matrix metalloproteinases that are secreted from cells or bound to the cell surface and degrade extracellular matrix molecules.

Proteinase Proteolytic enzymes, also known as proteases or endopeptidases, that hydrolyze internal peptide bonds of proteins and polypeptide chains (cf. exopeptidase, enzymes that hydrolyze one or a few amino acids from the N- or C-terminus of polypeptides).

TIMP An acronym for tissue inhibitors of metalloproteinases with molecular masses of 22–30 kDa that inhibit MMPs.

Matrix metalloproteinases (MMPs), also called matrixins, are a family of structurally related proteolytic enzymes in the Metzincin clan, containing a zinc ion liganded to three histidines in the active site. They are secreted from cells or are bound to the plasma membrane and hydrolyze extracellular matrix (ECM) and cell-surface molecules. As exemplified by the discovery of collagenase in the tadpole tail undergoing metamorphosis, MMPs play key roles in embryonic development, organ morphogenesis, ovulation, embryo implantation, nerve growth, bone remodeling, wound healing, angiogenesis, and apoptosis. Aberrant activities of MMPs are often associated with the progression of diseases such as cancer, arthritis, cardiovascular disease, nephritis, neuro-degenerative diseases, periodontal disease, skin ulceration, gastric ulcer, corneal ulceration, liver fibrosis, emphysema, fibrotic lung, and many others. Many cell types have the ability to synthesize MMPs but their production and turnover (transcription, translation, and cellular trafficking) are tightly controlled by growth factors, cytokines, physical stress to the cell, oncogenic transformation, hormones, and cell–cell and cell–ECM interactions. MMP activities are also regulated at the level of proteolytic and oxidative activation of the precursor zymogens, interaction with ECM and cell-surface molecules, and inhibition by endogenous inhibitors.

MMP Family

MMPs are found in vertebrates, fruit flies (*Drosophila melanogaster*), nematodes (*Caenorhabditis elegans*), sea urchins (*Paracentrotus lividus*), hydras (*Hydra vulgaris*), and plants (e.g., *Arabidopsis thaliana* and *Glycine max*). The human genome has 24 MMP genes (one gene duplication). There are two genes in *Drosophila*, six genes in *C. elegans*, and five genes in *Arabidopsis*. They are classified as the matrixin subfamily of metalloprotease family M10 in the MEROPS database. Vertebrate matrixins are assigned with MMP numbers and trivial names in many cases (Table 1). MMP numbers missing in the list (i.e., MMP-4, -5, -6, and -22) were found to be identical to one of the other MMPs. Expression of individual MMPs varies depending on cell types (Figure 1).

Most MMPs consist of a prodomain, a catalytic domain, a hinge (or linker), and a hemopexin domain. The signatures to assign proteinases to the MMP family are the cysteine switch motif with amino acid sequence PRCGXPD in the propeptide and the zinc-binding motif HEXGHXXGXXH in the catalytic domain, where the three histidines coordinate the zinc ion (Zn^{2+}). The primary structure of the catalytic domain is homologous to collagenase 1 (MMP-1). On the basis of substrate specificity sequence similarity and domain organization, MMPs are divided into six subgroups (Table 1 and Figure 2).

Table 1 Examples of substrates of mammalian MMPs

Enzyme	MMP	Human chromosome	Substrates
Soluble types			
<i>Collagenases</i>			
Interstitial collagenase (collagenase 1)	MMP-1	11q22–q23	Collagens I, II, III, VII, VIII, X, and XI, gelatin, entactin, tenascin, aggrecan, link protein, fibronectin, perlecan, IGFBP-2,-3,-5, α_1 PI, proIL-1 β , CTGF
Neutrophil collagenase (collagenase 2)	MMP-8	11q21–q22	Collagens I, II, and III, aggrecan, link protein, α_1 PI, substrate P
Collagenase 3	MMP-13	11q22.3	Collagens I, II, III, IV, IX, X, and XIV, gelatin, collagen telopeptides, fibronectin, aggrecan, tenascin, osteonectin, laminin, perlecan, CTGF, pro TGF β , MCP-3
Collagenase 4 (<i>Xenopus</i>)	MMP-18	–	Collagen I
<i>Gelatinases</i>			
Gelatinase A	MMP-2	16q13	Gelatin, collagens I, II, III, IV, V, VII, and X, fibronectin, laminin, aggrecan, elastin, tenascin, decorin, fibrillin, fibulin, galectin-3, plasminogen, α_1 PI, IL-1 β , IGFBP-3, FGFR1, MCP-3, pro TGF β , SDF-1, S100A8/9
Gelatinase B	MMP-9	20q12.2–q13.1	Gelatin, collagens IV, V, XI, XIV, XVIII, elastin, aggrecan, decorin, laminin, entactin, pro TGF β , α_1 PI, proIL-1 β , ICAM-1, galectin-3, IGFBP-3, IL-2 receptor α
<i>Stromelysins</i>			
Stromelysin 1	MMP-3	11q23	Collagens III, IV, V, IX, X, XI, XVIII, telopeptides of collagens I and II, gelatin, aggrecan, fibronectin, laminin, entactin, tenascin, decorin, myelin basic protein, α_1 PI, proIL-1 β , HB-EGF, CTGF, E-cadherin, IGFBP-3, activation of proMMP-1, proMMP-3, proMMP-7, proMMP-8, proMMP-9, proMMP-13, plasminogen, uPA
Stromelysin 2	MMP-10	11q22.3–q23	Collagen III, IV, and V, gelatin, fibronectin, elastin, aggrecan, activation of proMMP-1, proMMP-7, proMMP-8, proMMP-9
Stromelysin 3	MMP-11	22q11.2	α_1 PI (mouse MMP-11 has weak activities on collagen IV, gelatin, fibronectin, laminin, aggrecan), IGFBP-1
<i>Matrilysins</i>			
Matrilysin 1	MMP-7	11q21–q22	Collagen IV, XVIII, gelatin, aggrecan, link protein, elastin, fibronectin, vitronectin, laminin, SPARC, entactin, decorin, myelin basic protein, tenascin, fibulin, α_1 PI, proTNF α , E-cadherin, syndecan-1, pro α -defensin, activation of proMMP-1, proMMP-2, proMMP-9
Matrilysin 2	MMP-26	11p15	Collagen IV, fibronectin, fibrinogen, vitronectin, gelatin, α_1 PI, proMMP-9
<i>Others</i>			
Metalloelastase	MMP-12	11q22.2–q22.3	Elastin, collagen IV, gelatin, fibronectin, vitronectin, laminin, entactin, aggrecan, nidogen, myelin basic protein, osteopontin, α_1 PI, proTNF α , plasminogen, apolipoprotein a
(No name)	MMP-19	12q14	Collagen IV, laminin, entactin, tenascin, fibronectin, gelatin, aggrecan, COMP, IGFBP-3
Enamelysin	MMP-20	11q22.3	Ameloblastin, amelogenin, collagen XVIII, aggrecan, COMP
(No name)	MMP-21	10	Gelatin, α_1 PI
CA-MMP	MMP-23*	1p36.3	Gelatin
(No name)	MMP-27	11q24	–
Epilysin	MMP-28	17q21.1	Casein, Nogo-A, NCAM-1
Membrane types			
<i>Transmembrane</i>			
MT1-MMP	MMP-14	14q11–q12	Collagens I, II, and III, gelatin, fibronectin, vitronectin, laminins 1 and 5, syndecan-1, entactin, aggrecan, fibrin, α_1 PI, decorin, proTNF α , CD44, tissue transglutaminase, activation of proMMP-2 and proMMP-13
MT2-MMP	MMP-15	8q21	ProMMP-2, collagen I, collagen IV NCI domain, laminin, fibronectin, tenascin, entactin, aggrecan, perlecan, proTNF α , proMMP-2, tissue transglutaminase
MT3-MMP	MMP-16	15q13q21	ProMMP-2, collagen III, fibronectin, tissue transglutaminase
MT5-MMP	MMP-24	20q11.2	ProMMP-2, proteoglycans, gelatin
<i>GPI-anchored</i>			
MT4-MMP	MMP-17	12q24.3	Fibrinogen, fibrin, gelatin, proTNF α
MT6-MMP	MMP-25	16q13.3	Collagen IV, gelatin, fibrinogen, fibrin, fibronectin, proMMP-2

Further details are available in <http://www.merops.co.uk/merops/merops.htm> and references therein.

Collagenases

Collagenase 1 (MMP-1), collagenase 2 (MMP-8), collagenase 3 (MMP-13), and collagenase 4 in *Xenopus* (MMP-18) belong to this subgroup. The characteristic feature of these enzymes

is their ability to cleave native fibrillar collagen types I, II, and III into $\frac{3}{4}$ and $\frac{1}{4}$ fragments. Some members of other MMP subgroups also degrade fibrillar collagen (e.g., MMP-2 and MMP-14). Collagenases also digest other ECM and non-ECM proteins (Table 1).

Figure 1 Tissue expression of MMPs. Representative MMPs produced by various cell types are shown. The production of these MMPs is usually transcriptionally controlled by stimulatory factors.

Soluble MMPs

Membrane-type MMPs

Transmembrane

GPI-anchored

Figure 2 Domain arrangements of vertebrate MMPs.

Gelatinases

Gelatinase A (MMP-2) and gelatinase B (MMP-9) are in this subgroup. They have three repeats of fibronectin type II motifs inserted within the catalytic domain, which distinguishes them

from other MMPs. These repeats interact with collagens, gelatins, and laminin. Both MMPs readily digest denatured collagens, that is, gelatins, and a number of ECM molecules (Table 1). MMP-2, but not MMP-9, cleaves collagen I, II, and III into $\frac{3}{4}$ and $\frac{1}{4}$ fragments. MMP-2 is an important enzyme for

the release of matrix sequestered growth factors and cytokines and the processing of chemokines.

Stromelysins

Stromelysin 1 (MMP-3), stromelysin 2 (MMP-10), and stromelysin 3 (MMP-11) are assigned to this subgroup. While MMP-3 and MMP-10 have similar enzymatic properties, including their abilities to cleave various ECM molecules and activate several other MMPs (Table 1), MMP-11 has a more divergent amino acid sequence and substrate specificity. Human MMP-11 does not cleave ECM components. Alternative splicing and promoter usage generate an intracellular form of MMP-11.

Matrilysins

Matrilysin 1 (MMP-7) and matrilysin 2 (MMP-26) are assigned to this subgroup. They consist of a pro-domain and the catalytic domain only (Figure 2). MMP-7 is produced in epithelial cells and secreted apically. Besides digesting ECM molecules, it processes pro- α -defensin, Fas ligand, protumor necrosis factor α , and E-cadherin from the cell surface. MMP-26 digests several ECM molecules (Table 1).

Membrane-Type MMPs (MT-MMPs)

There are six MT-MMPs in humans. They are numerically assigned from MT1-MMP to MT6-MMP; four are type I trans-membrane proteins (MMP-14, MMP-15, MMP-16, and MMP-24) and two are glycosylphosphatidylinositol (GPI)-anchored proteins (MMP-17 and MMP-25). The catalytic domain and the hemopexin domain are exposed on the cell surface. With the exception of MT4-MMP (MMP-17), MT-MMPs activate proMMP-2 as well as digest ECM components. MT1-MMP, MT2-MMP, and MT3-MMP digest fibrillar collagens to varying degrees, and MT1-MMP activates proMMP-13. While MT1-MMP is expressed in many cell-types, MT5-MMP is expressed in brain, mainly in the cerebellum, and MT6-MMP in leukocytes.

Other MMPs

Seven MMPs do not belong to the above subgroups. Metalloelastase (MMP-12) is primarily expressed in macrophages. It digests elastin and other proteins and is essential for macrophage migration. The hemopexin domain of MMP-12 has bactericidal activity. MMP-19 is widely expressed in human tissues and implicated in tissue remodeling, wound healing, keratinocyte proliferation and migration, T-cell development, and T-cell-mediated immune responses. Enamelysin (MMP-20) is mainly expressed in newly formed tooth enamel. It processes amelogenin, and resulting products are essential for tooth enamel formation. MMP-21 is expressed in various fetal and adult tissues and in several invasive cancer cells. It digests gelatin and α_1 -proteinase inhibitor. MMP-23 is mainly

expressed in reproductive tissues. Two identical copies of the MMP-23 gene are located in human chromosome 1p36 loci in a head-to-head arrangement. The enzyme is a type II trans-membrane protein with a membrane-anchoring sequence located in the N-terminal end of propeptide. The propeptide is removed by a proprotein-converting proteinase; therefore, it is secreted from the cell as an active enzyme. The enzyme lacks both the cysteine switch motif in the propeptide domain and a hemopexin domain. The latter is replaced by a cysteine array and an immunoglobulin domain. MMP-27 is an ortholog of chicken MMP (originally assigned as MMP-22) and is expressed in B lymphocytes. The chicken enzyme digests gelatine and casein, but physiological substrates are not known. The enzymatic properties of MMP-27 have not been characterized. Epilysin (MMP-28) is expressed in keratinocytes, and its expression increases during wound healing. Its expression is also elevated in cartilage of patients with osteoarthritis and rheumatoid arthritis. Overexpression of MMP-28 in adenocarcinoma cells results in epithelial to mesenchymal transition, accompanied by loss of E-cadherin and activation of TGF β .

Structural Chemistry

The propeptide domain plays a key role in maintaining the MMPs in their zymogen forms (proMMPs) by blocking the active site. It has ~80 amino acids and consists of three α -helices and extended peptides including the cysteine switch motif (Figure 3(a)). The residues in the cysteine switch interact with the substrate-binding cleft in the catalytic domain by forming β -structure-like hydrogen bonds in a manner similar to a substrate, but in the opposite direction. The cysteine residue coordinates with the catalytic Zn²⁺ to maintain the latency of the enzyme.

Figure 3 Three-dimensional structure of MMPs and TIMPs. (a) Ribbon diagram of proMMP-2. The propeptide (pro) is shown in orange; the catalytic (cat) domain in green; the fibronectin (FN) domain in pink; and the hemopexin (Hpx) domain in red. Zinc ions and calcium ions are in pink and gray, respectively. (b) The catalytic domain of MMP-1 with a peptide substrate (stick representation) bound to the active site. (c) The complex of TIMP-1 and the catalytic domain of MMP-3.

The catalytic domain has ~170 amino acids including the zinc-binding motif (HEXGHXXGXXH) and a conserved methionine that forms a unique Met-turn structure. The domain consists of three α -helices, a five-stranded β sheet, and bridging loops (Figure 3(b)). It contains two zinc ions (Zn^{2+}): one is essential for catalysis and the other together with three calcium ions stabilizes the structure. The overall polypeptide folds, including the Met-turn, are similar to those of astacins, reprolysins, ADAMs, and bacterial proteinases serralsins, which together constitute the metzincins.

The hemopexin domain consists of ~190 amino acids and forms a four-bladed β -propeller structure arranged almost symmetrically around a central axis, and each blade is comprised of a four-stranded anti-parallel β sheet (Figure 3(a)). The domain is stabilized by a calcium ion and a disulfide bond between blades I and IV.

The catalytic domain and the hemopexin domain are connected by a hinge (also called linker) region of variable length, which does not have a specific structure. The fibronectin type II motif found in MMP-2 and MMP-9 consists of two double-stranded anti-parallel β -sheets and two large loops (Figure 3(a)). Each β -sheet has one disulfide bond. Several MMPs are glycoproteins. In particular, proMMP-8, proMMP-9, and proMMP-23 are highly glycosylated, with ~20–45% of their molecular mass being carbohydrate.

Mechanism of Peptide Bond Hydrolysis

The active site of MMPs consists of the catalytic Zn^{2+} bound to three imidazoles of histidines in the HEXGHXXGXXH motif and the glutamate in the motif. A proposed mechanism of peptide bond hydrolysis by MMPs is shown in Figure 4. In an active MMP, one water molecule is bound to the catalytic Zn^{2+} . Upon binding of a peptide substrate to the active site of the enzyme, the carbonyl group of the P1 residue interacts with the catalytic Zn^{2+} and the water molecule is displaced toward the carboxyl group of the glutamate. This polarizes the water molecule and promotes its nucleophilic attack on the carbonyl carbon of the scissile bond, resulting in formation of a hemiketal intermediate and the subsequent hydrolysis of the peptide bond. The glutamate functions as a general acid/base during catalysis. Mutation of the glutamate to aspartate reduces the enzymatic activity to less than 1% and mutation to alanine reduces activity to 0.01% of the wild type.

Activation of proMMPs

MMPs are synthesized as pre-pro-MMPs and many are secreted from cells as zymogens (proMMPs) which need to be activated outside the cell. The major activation pathways are proteolytic processes, which can include auto-cleavages.

Figure 4 A proposed mechanism of action of MMPs. A peptide substrate and a water molecule that are involved in hydrolysis are shown red and blue, respectively. The residues shown are in MMP-1. See text for details.

Activation by Proteinases

The six MT-MMPs and MMP-11, -21, -23, and -28 contain a furin-like proprotein converting proteinase recognition sequence at the C-terminal end of the propeptide domain. Most of them are therefore activated within the cell and secreted or bound to the membrane as the active form.

Other MMPs are secreted from cells as proMMPs in the tissue. ProMMPs are likely to be activated by tissue or plasma proteinases or opportunistic bacterial proteinases. Figure 5 illustrates activation pathways that are involved in pericellular ECM hydrolysis. The urokinase-type plasminogen activator/plasmin system initiates the activation of many proMMPs near the cell surface. Unlike many other MMPs, proMMP-2 is not readily activated by plasmin or other proteinases, but activated on the cell surface by MT1-MMPs. This activation process is assisted by binding to a TIMP-2-MT1-MMP complex which presents proMMP-2 to an adjacent active MT1-MMP. ProMMP-13 is also activated by MT1-MMP, but this does not require TIMP-2 (Figure 5).

Activation by Chemical and Physical Means

ProMMPs can be activated *in vitro* by SH-reactive agents (e.g., 4-aminophenylmercuric acetate, iodoacetamide, and oxidized glutathione), chaotropic agents (e.g., urea, SCN^- , I^-), sodium dodecylsulfate, reactive oxygen, low pH, and heat treatment. This is due, in part, to the disruption of the cysteine–zinc interaction formed between the propeptide and catalytic domains and subsequent removal of the propeptide by autoproteolysis. Oxidation may activate some proMMPs, but it may also destroy the enzyme.

Activity and Substrate Specificity

MMPs exhibit optimal proteolytic activities at around pH 7.0–8.0 for most substrates, but, in some cases, they exhibit a broader pH range. An exception is human stromelysin 1 which has optimal activity at around pH 5.5–6.0 with a shoulder of activity at pH 7.5–8.0.

MMPs degrade ECM and non-ECM proteins (see Table 1 for representative substrates), indicating roles in many cellular processes. The potential substrates of more recently discovered MMPs (higher numbers) have not been well characterized. In general, the substrate needs to be six amino acids or longer, and the enzymes have a strong preference for hydrophobic residues at the P1' site (the residue located on the right of the cleaved peptide bond) such as Leu, Ile, Met, Phe, or Tyr, but the amino acid at the P1 site (the residue on the left of the cleaved peptide bond) is not important. Nuncatalytic domains greatly influence substrate specificity for some MMPs when substrates are extracellular macromolecules; for example, fibronectin domain repeats of MMP-2 and MMP-9 play an important role in expressing the activity on type IV collagen, gelatin, and elastin; and the hemopexin domain of collagenases is essential for the collagenolytic activity.

MMPs are inhibited by chelating agents such as EDTA, 1,10-phenanthroline, cysteine, and dithiothreitol. Numerous synthetic inhibitors of MMPs have been designed. They commonly contain a zinc-chelating moiety such as a hydroxamic acid, a carboxyl, a thiol, or a phosphinic group, although more recent developments have tended to avoid zinc chelators. Some highly selective inhibitors for specific MMPs have been generated, notably focusing on the S1' pocket, but many still broadly inhibit MMPs and other metalloproteinases. Phosphoramidon is not inhibitory. Tissue inhibitors of metalloproteinases

Figure 5 Activation pathways of proMMPs involved in pericellular ECM proteolysis. Urokinase-like plasminogen activator (uPA) bound to uPA receptor (uPAR) activates plasminogen to plasmin, which in turn activates a number of proMMPs. MT1-MMP activates proMMP-2; this process is assisted by binding to the TIMP-2-MT1-MMP complex which presents proMMP-2 to an adjacent active MT1-MMP. Activation of proMMP-13 by MT1-MMP does not require TIMP-2. Activated MMPs also participate in the activation of other proMMPs. Active enzymes are boxed.

(TIMPs), $\alpha 2$ -macroglobulins, and ovomacroglobulins (ovostatins) are the known natural protein inhibitors.

Endogenous Inhibitors of MMPs

$\alpha 2$ -Macroglobulins

Human $\alpha 2$ -macroglobulin is a plasma glycoprotein of 725 kDa consisting of four identical subunits of 180 kDa. It inhibits most endopeptidases by a trap mechanism: the interaction with a proteinase is initiated by the proteolytic cleavage in the middle of the subunits, causing a conformational change in the macroglobulin, hence entrapping the proteinase molecule. The active site of the trapped proteinase is not blocked, but its access to large protein substrates is sterically hindered. Related macroglobulins in other species, including ovomacroglobulins (ovostatins), have a similar inhibition mechanism.

TIMPs

TIMPs are structurally related proteins which inhibit matrixins with a 1:1 molar stoichiometry. The human genome has four TIMP genes and there are two genes in *C. elegans* and one in *Drosophila*. The four human isoforms (TIMP-1 to -4) consist of 184–194 amino acids, subdivided into N-terminal and C-terminal domains, each having three disulfide bonds. The N-terminal domain is the inhibitory domain and it binds to the active site of the MMPs. ProMMP-2 and proMMP-9 zymogens of MMPs bind to TIMPs via interaction between the C-terminal noninhibitory domain of TIMP and the C-terminal hemopexin domain of proMMP. These complexes act as MMP inhibitors since the N-terminal inhibitory domain of TIMPs is not blocked. TIMP-3 is unique among four TIMPs as it also inhibits ADAMs and ADAMTSs, metalloproteinases containing a disintegrin domain.

Inhibition Mechanism

The inhibitory domain of TIMPs has an OB-fold structure with a reactive ridge formed by the N-terminal segment Cys¹-Thr-Cys-Val⁴ and the Ser⁶⁸-Val-Cys⁷⁰ (residues are in TIMP-1) where Cys¹ and Cys⁷⁰ are disulfide linked. This ridge structure slots into the active site cleft of the MMPs (Figure 3(c)). The nitrogen of the N-terminal NH₂-group and the carbonyl oxygen of Cys¹ bidentately chelate the Zn²⁺ in the active site of the enzyme. MMPs do not form covalent bonds with TIMPs nor cleave TIMPs, but form tight complexes with inhibition constants in the sub nanomolar range.

Biological Activities of MMPs

The main function of MMPs is considered to be removal of ECM macromolecules from the tissues; they also alter the function of ECM molecules by specific proteolysis and express new biological functions of these molecules. Some secreted MMPs bind to specific cell-surface receptors, membrane-anchored proteins, or cell-associated ECM. This allows them to function in a focused way to modulate the pericellular environment. MMPs can also release growth factors bound to

ECM and from carrier proteins, or inactivate inflammatory cytokines and chemokines, which then influence cellular behavior. For example, the cleavage of type I collagen is associated with keratinocyte migration during wound healing, activation of osteoclasts during bone remodeling, and induction of apoptosis of amnion epithelial cells before the onset of labor. Cleavage of laminin 5 and CD44 by MMPs promotes cell migration. The expression of MT1-MMP and activation of proMMP-2 occur in invasive tumor cells and endothelial cells at the migratory front and promotes cells to migrate and invade by cleaving and shedding these ECM and cell-surface molecules. The release of TGF β and VEGF from the matrix by MMPs modulates ECM synthesis and angiogenesis, respectively, which are key events in development, morphogenesis, reproduction, tissue remodeling, and repair. Inactivation of monocyte chemoattractant proteins or interleukin 1 β by MMP reduces inflammation. MMPs are now acknowledged as modulators of many extracellular signaling pathways, with individual specificities for associated proteins, including cytokines, growth factors, cell adhesion molecules, and others.

Human Genetic Disorders and DNA Polymorphisms

Unregulated MMP activities are implicated in the progression of a variety of diseases characterized by aberrant breakdown of ECM molecules. In many cases, their activities are controlled at the cellular level by various stimulatory factors. In addition, a few inherited human disorders associated with the MMP and TIMP genes have been described.

Mutations in human MMP-2 resulting in the absence of active MMP-2 are linked to a rare autosomal recessive genetic disorder, multicentric osteolysis (Torg syndrome, nodulosis–arthropathy–osteolysis syndrome, and Winchester syndrome), which causes destruction of the affected bones and joints. A mutation in the coding region for MMP-13 is associated with spondyloepimetaphyseal dysplasia, a dwarfism resulted from abnormal development of the vertebrae and extremities. Amelogenin imperfecta, a genetic disorder caused by defective enamel formation, is due to a mutation at MMP-20 cleavage sites.

Mutations in the coding region of the TIMP3 gene leading to the presence of an extra Cys in the C-terminal region of the expressed protein cause the rare autosomal dominant Sorsby's fundus dystrophy, a form of blindness characterized by death of the retinal pigment epithelium.

Various DNA polymorphisms in MMP genes are associated with a number of diseases. In many cases, polymorphic sites are found in the promoter regions of MMP genes: polymorphisms in the *MMP1* gene are associated with coronary heart disease, rheumatoid arthritis, periodontitis, and cancers (e.g., cervix, ovary, colon, kidney, lung, and skin); in the *MMP2* gene with the risk of developing lung cancer; in the *MMP3* gene with coronary heart disease, coronary aneurysms, and cancers (colon and breast); in the *MMP9* gene with coronary heart disease, aneurysms, nephropathy, and preterm prenatal rupture of the fetal membrane; and in the *MMP12* gene with coronary atherosclerosis.

Glossary

Argonaute A family of proteins that bind micro-RNAs to form a functional RNA-induced silencing complex. Some members of the Argonaute family possess RNase H-like activity and are able to cleave target messenger RNA (mRNA) transcripts, while other members of the Argonaute family lack RNase-H like activity and inhibit translation of mRNA by other means.

Micro-RNA A small RNA molecule found in eukaryotes, typically ~22 nucleotides in length, that is excised from an endogenous double-stranded RNA precursor containing a stem-loop structure.

Mirtron A micro-RNA precursor that is spliced out of an intron.

RNA-induced silencing complex A multiprotein complex that binds a mature micro-RNA and then targets a complementary RNA transcript to inhibit translation.

Small RNA Eukaryotic noncoding RNAs ~18–24 nucleotides in length that often have regulatory roles in cells. Classes of small RNAs include: micro-RNA, small nuclear RNA, small nucleolar RNA, piwi-interacting RNA, small interfering RNA and trans-acting small interfering RNA.

MicroRNAs in Eukaryotes

Several classes of noncoding small RNAs, RNA molecules consisting of ~18–24 nucleotides (nt), are found in eukaryotes. MicroRNAs (miRNAs) are a distinct subclass of small RNA molecules that are ~21–23 nt long. miRNAs arise from endogenous, double-stranded hairpin-shaped RNAs and they function to silence endogenous genes at transcriptional and/or posttranscriptional levels in eukaryotes. miRNAs inhibit transcription by guiding an RNA-induced silencing complex (RISC) to cleave a complementary messenger RNA (mRNA) transcript. Alternatively, miRNAs may prevent translation of an mRNA by targeting a RISC to an mRNA to impede the action of ribosomes by one of several possible mechanisms including deadenylation, ribosome inhibition, or repression of translation initiation. The importance of miRNAs is underscored by the discovery that many miRNA families are conserved across distant taxa and that upward of 50% of all protein-coding mammalian genes are miRNA targets. Although small in size, up to 10 000 individual miRNAs may be present in a single cell and they function in myriad biological processes including plant and animal development, epigenetics, and cancer growth.

miRNAs are very similar to another class of small RNAs termed 'short interfering RNAs' (siRNAs) that require the same families of proteins, Dicers and Argonautes (see below), to silence their targets. siRNAs were once thought of as arising only when a virus, transgene, or transposon was attacking a genome, whereas miRNAs were endogenously encoded. However, recent research has shown that siRNAs are not always exogenous in origin, and the distinction between miRNAs and siRNAs is beginning to become more obscured. Today, the major difference between siRNAs and miRNAs is that siRNAs originate from within fully complementary double-stranded RNAs (dsRNAs), while miRNAs are derived from a dsRNA that takes on a stem-loop conformation with imperfect complementarity.

Discovery of miRNAs

The first clues to the existence of small RNAs as a mediator of gene silencing arose in the mid-1980s, when researchers injected anti-sense RNA into a murine (*Mus musculus*) cell line and observed a decrease in the accumulation of the corresponding sense RNA transcript. It was soon discovered that similar experiments with frog (*Xenopus* sp.) oocytes, fruit fly (*Drosophila melanogaster*) embryos, and wild carrot (*Daucus carota*) protoplasts also reduced the accumulation of complementary endogenous mRNAs, which indicated that this phenomenon was widespread in eukaryotes.

A major breakthrough in small RNA research occurred in 1993, when the first miRNA was discovered in the nematode *Caenorhabditis elegans*. The *lin-4* locus encodes a product required for heterochronic switching in post-embryonic development by repressing the accumulation of the LIN-14 protein and allowing for properly timed switches between larval developmental stages. The *lin-4* loss-of-function mutants revert to early developmental stages later in development, which can lead to the absence of typical adult structures. Intriguingly, the *lin-4* locus was not found to encode a protein. The *lin-4* locus produces 22- and 61-nt RNA transcripts that are complementary to seven repeats in the 3' untranslated region (UTR) of *lin-14* mRNA in *C. elegans*. The discovery that *lin-4* RNA transcripts could bind *lin-14* mRNA strongly suggested that *lin-4* inhibits *lin-14* via an antisense RNA–RNA interaction. However, *lin-14* mRNA levels are unaltered in *lin-4* loss-of-function mutants, so it was believed that *lin-4:lin-14* RNA–RNA interactions inhibited *lin-14* mRNA translation rather than transcription. Several years later, the second miRNA locus, *let-7*, was also discovered in *C. elegans*. Researchers showed that *let-7*, another heterochronic switching factor, produces a 21-nt miRNA that has complementarity to several additional heterochronic switching factors including *lin-14*. Early work in *C. elegans* demonstrated that miRNAs were intricately linked to developmental timing,

Figure 1 MicroRNA biogenesis in plant and animal cells. (a) In plant cells DICER-LIKE1 (Dcl1) processes the primary microRNA (pri-miRNA) into a precursor miRNA (pre-miRNA) and then to a ~22-nt-long miRNA/miRNA* duplex in the nucleus. The miRNA/miRNA* duplex is exported from the nucleus to the cytoplasm where it is loaded into an ARGONAUTE (AGO) protein to form a functional microRNA-induced silencing complex (miRISC). (b) In animal cells Drosha, a protein similar to DCL1, processes pri-miRNAs into pre-miRNAs with DGCR8, a double-stranded RNA binding protein. Alternatively, the spliceosome can excise pre-miRNAs from mRNA introns. Unlike in plants, the pre-miRNA is exported from the nucleus to the cytoplasm before being processed into a mature miRNA/miRNA* duplex. The pre-miRNA is processed in the cytoplasm by Dicer and a transactivation-responsive RNA-binding protein (TRBP). From there the miRNA and miRNA* may be incorporated into an AGO miRISC with the aid of a glycine-tryptophan protein of 182 kilodaltons (GW182). Reproduced from Carthew RW and Sontheimer EJ (2009) Origins and mechanisms of miRNAs and siRNAs. *Cell* 136: 642–655, with permission from Elsevier.

and subsequent work soon showed that miRNAs are abundant in many invertebrate and vertebrate species. Around the same time, researchers began to identify miRNAs in plants as well, indicating that miRNAs likely originated early in eukaryote evolution prior to the split between animals and plants.

Biogenesis of miRNAs

Upward of 1000 discrete miRNAs may be encoded in a single genome and they are all inexorably linked to a small group of proteins required to process the miRNAs in the nucleus, export them from the nucleus to the cytoplasm, and act on the target gene to inhibit transcription or translation. While most plant miRNA loci are found singly in intergenic regions and individually transcribed by their own promoters, animal miRNAs are often found in clusters, within introns of protein-coding genes, and/or transcribed in polycistronic units. miRNA loci in plants and animals are typically transcribed by RNA polymerase II (Pol II), and these primary miRNA (pri-miRNA) transcripts are capped with 7-methylguanylate on the 5' end and polyadenylated on the 3' end. The pri-miRNA folds back on itself in an imperfect manner to form a stem-loop structure and may be several thousand nucleotides long, although the stem is usually only ~33 nt long. Biogenesis of miRNAs is similar in plants

(Figure 1(a)) and animals (Figure 1(b)), but there are several subtle differences between the two kingdoms.

An RNA-binding protein, DAWDLE in plants or the orthologous SNIP1 in animals, stabilizes pri-miRNAs as they are readied for processing into precursor miRNAs (pre-miRNAs). In plants, pri-miRNAs are moved to a nuclear processing region called a D-body where it interacts with a protein complex that includes HYPONASTIC LEAVES1, a dsRNA-binding protein, SERRATE, a C2H2-zinc finger protein, and DICER-LIKE1 (DCL1), which transforms the pri-miRNA into a ~60–70-nt-long hairpin-shaped pre-miRNA. DCL1 is an RNase III family member and consists of several domains, including a DEXD/H ATPase domain, a domain of unknown function (DUF) 283 domain, an RNA helicase motif, a Piwi/Argonaute/Zwille (PAZ) domain to hold the 3' end of small RNA molecules, two RNase III domains, and one or more dsRNA-binding domains. DCL1 is the enzyme that physically cleaves the pri-miRNA into the pre-miRNA in plants. Following a second round of processing by DCL1, in which the pre-miRNA is reduced to a ~22-nt dsRNA consisting of the mature miRNA and its antisense complement, or passenger strand (miRNA*), the resulting miRNA/miRNA* duplex is methylated and stabilized by HUA ENHANCER1, an S-adenosyl methionine-dependent methyltransferase. Methylation prevents the miRNA from being degraded by a family of small RNA-degrading nucleases in

the cytoplasm. The miRNA/miRNA* duplex is exported from the nucleus to the cytoplasm via the animal Exportin-5 homolog HASTY, although there are likely additional miRNA/miRNA* nuclear export pathways in plants as some miRNAs are still exported from the nucleus in *hasty* loss-of-function mutants. It is also not entirely clear where or when the miRNA and miRNA* separate in plants, but once in the cytoplasm the miRNA associates with an ARGONAUTE (AGO) protein to form a RISC, which may then target transcripts with complementarity to the miRNA. AGO proteins consist of an N-terminal domain, a PAZ domain, which is shared with DCL and Dicer (see below) proteins, a middle (MID) domain to hold the 5' end of a small RNA molecule and a P-element-induced Wimpy testis (PIWI) domain, which has RNase H-like activity to cleave target transcripts.

In animal nuclei, the pri-miRNA interacts with Drosha, an RNase III family member similar to, but not homologous to, DCL1, and DGCR8/Pasha, a dsRNA-binding protein that helps to position the catalytic residues of Drosha at the correct position on the pri-miRNA. Drosha is responsible for cleaving the pri-miRNA into the much smaller pre-miRNA. The pre-miRNA is immediately processed into the miRNA/miRNA* duplex in plants, but in animals the pre-miRNA is exported from the nucleus to the cytoplasm via Exportin-5. Once it reaches the cytoplasm, the pre-miRNA is loaded into a complex including Dicer, AGO2, and a transactivation-responsive RNA-binding protein. Although plant genomes often encode multiple DCL family members that are able to specialize to only process either miRNAs or siRNAs, the genomes of mammals and *C. elegans* encode only one Dicer protein, which processes both miRNAs and siRNAs. The pre-miRNA is processed into an miRNA/miRNA* duplex by Dicer. The duplex has a short life span, and either strand may be incorporated into a functional RISC, although the more stable strand is termed the 'miRNA' and is transferred to AGO more often than miRNA*, which is often degraded. However, miRNA* has occasionally been found to be able to form a functional RISC and target mRNA transcripts, adding a new wrinkle to miRNA biogenesis.

Animals also have many miRNAs transcribed from within introns rather than from intergenic regions, and these loci are called 'mirtrons'. Mirtron expression is regulated by the promoter of its host transcript and they are transcribed by Pol II as a canonical gene transcript, but when the spliceosome removes the intron containing the miRNA, it is spliced out as a pre-miRNA. This pre-miRNA then undergoes normal processing on its way to becoming a mature miRNA.

Function of miRNAs

Once an miRNA has been generated and joins a functional RISC, it will guide the RISC to a complementary sequence on an mRNA transcript. Animal miRNAs often have imperfect complementarity with their targets and they usually target sequences in the 3' UTR of the mRNA transcript. Recent work suggests that ~60% of murine miRNA target sequences are in the 3' UTR, while 25% are in exons and 12% are within introns. In contrast to animals, plant miRNAs typically have perfect complementarity with their target transcripts and the targeted base pairs are generally within an exon.

The miRNA-guided RISC can regulate target transcripts in both plants and animals either by cleaving the transcript or by inhibiting translation of the transcript into a protein. Not all AGO family members have the ability to cleave target transcripts, and those that do have this ability are often referred to as 'slicers'. The miRNA itself also is an important determinant in regard to whether or not a target mRNA can be cleaved. If the miRNA does not have perfect complementarity with the target between nucleotides 9 and 11, a bulge in the miRNA-mRNA duplex will form and the active site residues of AGO will not be properly positioned to cleave the target mRNA, which will likely lead to translational inhibition. However, if there is perfect complementarity between the miRNA and the targeted mRNA, then endonucleolytic cleavage of the mRNA is possible. The discovery of *miRNA-action deficient* mutants in *Arabidopsis* showed that mRNA cleavage and translational inhibition are equally likely to occur in plants, genetically separable, and that translational inhibition is the default method for miRNA-mediated gene silencing in plants and animals.

There are several proposed models for posttranscriptional silencing via RISC activity in animals. It is not yet known if an miRNA-guided RISC prevents translation before or after initiation, although experimental data suggest that inhibition may occur at both stages. In order to begin mRNA translation in mammals, an eIF4F initiation complex recognizes the 5' cap on an mRNA and recruits other initiation factors and ribosomal subunits to the 5' end of the mRNA (Figure 2(a)). The recruitment process also causes the mRNA to circularize, which improves translation efficiency. One model of posttranscriptional silencing simply suggests that the presence of a RISC on an mRNA transcript promotes ribosomal drop-off, which would prevent translation from occurring (Figure 2(b)). A second model suggests that the MID domain of human AGO2, which resembles the structure of eIF4F, can compete with the initiation complex to bind the 5' cap on the mRNA (Figure 2(c)). If eIF4F is outcompeted by AGO2, then eIF4F would be unable to bring ribosomes to the translation start site and translation would not occur. A third proposed model suggests that a RISC may inhibit 60S ribosomal subunits from joining the translation initiation complex. *In vitro* experiments have shown that human AGO2 can bind the initiation factor eIF6 and 60S ribosomal subunits. eIF6 acts to keep 60S ribosomal subunits from prematurely interacting with 40S ribosomal subunits, so if eIF6 and 60S subunits were to bind AGO2, then the 60S subunits would be unable to bind 40S subunits and begin mRNA translation (Figure 2(d)). Finally, the fourth model proposes that the presence of a RISC on an mRNA promotes deadenylation of the poly(A) tail. The removal of adenosines is purported to inhibit circularization of the mRNA molecule, which would greatly decrease translational efficiency and effectively silence the mRNA transcript.

The *Arabidopsis* gene *VARICOSE* (VCS) is homologous to the mammalian gene *Ge-1*, a decapping enzyme required for miRNA-guided posttranslational inhibition. Loss-of-function *vcs* mutants show no increase in mRNA accumulation levels for miRNA targets, but protein levels do increase, which implies that VCS, like *Ge-1*, is required for posttranslational inhibition. This discovery shows that plants and animals likely use similar mechanisms to regulate mRNA at the posttranslational level with miRNA-guided RISCs.

Figure 2 Modes of microRNA silencing. Several possible mechanisms have been proposed for the regulation of mRNA transcripts by miRNA-guided RISC activity. (a) Efficient mRNA translation requires circularization of the mRNA. Eukaryotic translation initiation factors (eIF4E and eIF4G) bind to the 5' cap (CAP) of the mRNA and to poly(A)-binding proteins (PABPs) to circularize the mRNA and allow translation initiation by 40S and 60S ribosomal subunits. (b) eIF4E can begin to circularize mRNA transcripts, but miRNA-guided RNA-induced silencing complexes (RISCs) cause ribosomes to drop off the mRNA transcript and inhibit full mRNA translation. (c) The MID-domain (MC) of an Argonaute protein in a RISC may outcompete eIF4E to bind the 5' cap on miRNA-targeted transcripts and inhibit the start of mRNA translation. (d) The AGO protein in the RISC may bind eIF6, which binds the 60S ribosomal subunit. This binding could prevent the 60S and 40S ribosomal subunits from forming a translation complex. Reproduced from Tang G, Tang X, Mendu V, et al. (2008) The art of microRNA: Various strategies leading to gene silencing via an ancient pathway. *Biochimica et Biophysica Acta* 1779: 655–662.

Biological Roles of miRNAs

Any one miRNA may target several dozen distinct mRNA transcripts, and an mRNA transcript may be under the regulation of several miRNA species. miRNAs are prevalent in essentially all eukaryotic cells, so it is not surprising that they have adopted functions in diverse biological processes including, but not limited to, plant development, animal development, epigenetics, and cancer growth.

One of the most controversial aspects of current miRNA research in plants is whether or not miRNAs can act noncell autonomously, that is, whether or not they are mobile. Unlike in animals, plant cell fate is not determined by cell lineage; rather, it is established by positional clues from neighboring cells. Plant cells are known to rely on mobile signals to establish their fate, so if regulatory molecules such as miRNAs are mobile, it could have major implications in understanding how plants develop. Early research using artificial miRNAs and/or miRNAs with non-native promoters in plants suggested that miRNAs could only act in a cell-autonomous manner. However, recent research strongly suggests that plant miRNAs are in fact mobile and capable of acting some distance away from their origin via transport through phloem and/or plasmodesmata. Several lines of research support the idea of mobile miRNAs: several miRNAs known to respond to physiological stresses are readily found in phloem sap; in maize (*Zea mays*), *MIR390* precursor loci are expressed only in the outermost cell layer of the shoot apical meristem, but *in situ* hybridization shows that mature miR390 accumulates in inner cell layers as well as the outermost layer; lastly, it has been shown

that a mobile miRNA acts in a reciprocal manner with a mobile transcription factor to pattern the *Arabidopsis* root.

miRNAs also play important roles in animal development beginning with embryogenesis. The vital role of the miRNA biogenesis pathway in embryo development is underscored by Dicer knockouts in mice; they are embryonic lethal. However, stem cell populations that lack functional Dicer proteins have been recovered. Since these stem cells lack differentiation markers even after differentiation has been induced, and often show cell-cycle arrest, it can be inferred that miRNAs play an important role in the establishment of different tissue types during embryogenesis. Indeed, it has been revealed that distinct miRNA species play important roles in the formation of a diverse array of mammalian cell types.

Many studies have implicated siRNAs in directing epigenetic changes to an organism's genome, but miRNAs have also been shown to be vital to this process. Epigenetics encompasses changes to an organism's genome without changing the DNA sequence. Epigenetic changes may modify gene expression by causing methylation of individual DNA nucleotides and/or by methylating or acetylating histones, which can change the chromatin state back and forth from easily accessible euchromatin to inaccessible heterochromatin. miRNAs manipulate epigenetic changes by regulating the accumulation of DNA methyltransferases, which methylate DNA, and histone deacetylases and histone methyltransferases. Interestingly, many miRNA genes, perhaps up to 15% in humans, have been found to be targets for silencing by the very epigenetic machinery they target, indicating that a complex feedback loop likely regulates epigenetic changes. Similarly, in

Arabidopsis, miR168 has been shown to negatively regulate the accumulation of AGO1 mRNA, which indicates that miRNA genes and RISC-related genes are under tight regulation. Many of the epigenetic influences caused by miRNAs have been uncovered during research of various types of cancer. In most cancers, the overall expression of miRNAs is reduced, but individual miRNAs may increase their accumulation. Typically, oncogenes have increased accumulation due to a decrease in their regulatory miRNAs, while tumor-suppressor genes show decreased accumulation due to an increase in their regulatory miRNAs. Interestingly, it seems that each type of cancer has a distinct collection of miRNAs that could be used as biomarkers in the future to identify cancers in humans at the earliest stages of tumor development.

Conclusion

This article discusses the mechanisms of miRNA biogenesis. The exact mechanism of miRNA-guided RISC translational inhibition is currently unknown, but it likely involves several, if not all, of the proposed models covered herein. Since their discovery in 1993, the study of miRNAs has progressed rapidly and more will surely be uncovered in the years to come.

Microtubule-Associated Proteins

N Hirokawa, University of Tokyo, Tokyo, Japan

R Takemura, National College of Nursing, Tokyo, Japan

© 2013 Elsevier Inc. All rights reserved.

Glossary

Axon Structure that transmits the signal from the cell body to the synaptic terminal. Single axon extends from the cell body. Microtubules and neurofilaments are major components of the axonal cytoskeleton. Microtubules in the axons are organized more densely than in the dendrites.

Dendrite Structures that receive signals and transmit them to the direction of the cell body. Usually, multiple dendrites emanate from the cell body in 'dendritic' shape.

Microtubules are the major components of the dendritic cytoskeleton, and microtubules in the dendrites are organized more loosely than in the axon.

Microtubule Filament of 25 nm diameter.

Assembled from α - and β -tubulin subunits (55 kDa), it is actually a hollow cylinder (hence tubule) composed of 13 protofilaments. During mitosis, it forms a mitotic spindle. Compared to intermediate filaments (10 nm diameter), microtubules turn over much more dynamically. New subunits are added at the 'plus' end, while subunits dissociate from the 'minus' end (treadmilling). In addition, microtubules show the property called 'dynamic instability', in which individual microtubules are either growing or shrinking and they stochastically switch between the two states.

Classical Microtubule-Associated Proteins

Microtubules are formed by polymerization of α - and β -tubulin. Microtubules play important roles in organizing and maintaining the shape of the cell, and also act as tracks for the transport of membranous organelles and macromolecules. The so-called motor proteins (kinesin superfamily proteins and dynein superfamily proteins) are involved in the transport processes, and they use the energy derived from the hydrolysis of ATP. Microtubule-associated proteins (MAPs) bind to microtubules without a requirement for nucleotide involvement, and organize the spatial arrangement of microtubules within the cell; they also regulate the polymerization of microtubules. Historically, MAPs have been isolated from the mammalian brain by their property that they remain bound to microtubules through repeated cycle of polymerization and depolymerization. The quick-freeze, deep-etch microscopy reveals that in neurons, there are abundant filamentous structures of various length associated with microtubules. These filamentous structures were proved to be mainly composed of MAPs (Figures 1 and 2). These MAPs have been studied extensively, and we term these well-characterized MAPs as 'classical MAPs'. The major part of this article will be spent on these classical MAPs. Some other MAPs are known and some new MAPs have been identified recently. These will be dealt with in relevant places. Classical MAPs include MAP1A, MAP1B, MAP2A, MAP2B, MAP2C, and tau (from mammalian brains) and MAP4 (found ubiquitously) (Table 1). All these MAPs are fibrous molecules of different lengths, ranging from 50 to 185 nm, and form filamentous projections from the microtubule surface. First, the basic biochemical properties and their expression patterns will be described for each of the classical MAPs.

MAP1A and MAP1B

MAP1A and MAP1B are high-molecular-weight, heat-labile, filamentous proteins of ~350 and 320 kDa on sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). MAP1A and MAP1B are transcribed from the separate genes. MAP1B has also been called MAP1x or MAP5. The protein originally called MAP1C turned out to be cytoplasmic dynein. Therefore, it is not usually included in MAPs. MAP1A encodes protein of 2774 amino acid residues, and MAP1B encodes protein of 2464 amino acid residues. Rotary-shadowing electron microscopy reveals that MAP1A and MAP1B are highly elongated, flexible molecules of ~150–185 nm in length. Both MAP1A and MAP1B have associated light chains. Interestingly, the light chains, LC2 and LC1, are encoded at the C-terminal portion of MAP1A and MAP1B molecules, respectively. At the N-terminal portion of both MAP1A and MAP1B molecules, there is a domain enriched in the positively charged amino acids and contains the short motif (KKEX), repeated 11 and 21 times in MAP1A and MAP1B (Table 1 and Figure 3). This domain serves as microtubule-binding domain, and interacts with C terminus of tubulin, which has a large number of acidic residues. Both MAP1A and MAP1B form filamentous structures associated with microtubules in neurons.

MAP1A and MAP1B are predominantly expressed in neurons, although a smaller amount may be expressed in other tissues as well. There is a developmental regulation in the expression of MAP1. MAP1A is more abundantly expressed in the adult, and MAP1B is more abundantly expressed in the developing nervous system. In fact, the expression of these two proteins appears to be complementary to each other. In the rat brain development, the level of MAP1B expression is highest at the first few postnatal days, when many neurons are extending their axons. Thereafter, the expression of MAP1B declines.

Figure 1 Axonal cytoskeleton observed by quick-freeze, deep-etch electron microscopy. Between microtubules (thick black arrows), short cross-linkers (thin arrows) and longer cross-linkers are found. Scale = 100 nm. Reproduced from Hirokawa N (1991) Molecular architecture and dynamics of the neuronal cytoskeleton. Table 1 Characteristics of classical MAPs

MAPs	App. mol. weight on SDS-PAGE (kDa)	Number of amino acids	Length of isolated molecule (nm)	Distance in microtubule bundles (nm)	Microtubule-binding domain	Developmental and topological expression pattern
MAP1A ^a	350	2774	150–185		N-terminal KKEX repeats	Abundant in mature dendrite
MAP1B ^a	320	2464	150–185		Same as above	Abundant in developing axon
MAP2A ^b	280	1911	~100	~65	C-terminal tandem repeats	Specific to developing dendrite
MAP2B ^b	270	1828	~100	~65	Same as above	Specific to developing and mature dendrite
MAP2C ^b	70	467		~20	Same as above	Abundant in developing axon and dendrite
tau ^c	55–65	352–441	~50	~20	Same as above	Abundant in developing and mature axon
MAP4	210	1072			Same as above	Ubiquitously expressed

^aMAP1A and MAP1B are transcribed from separate genes.

^bMAP2A, MAP2B, and MAP2C are splice variants.

^cSix isoforms of tau are splice variants.

By contrast, the expression of MAP1A is very low at this period, but the level of its expression increases thereafter, and reaches its maximal level in adults. There is a spatial difference in the expression of MAP1B and MAP1A. MAP1B is predominantly expressed in the developing axon, although smaller amount is found in the dendrite of juvenile and mature neurons. By contrast, MAP1A is abundantly expressed in the mature dendrites, with the smaller amount of expression at the axons.

MAP2A, MAP2B, and MAP2C

MAP2A and MAP2B were identified as high-molecular-weight, filamentous protein of ~280 and 270 kDa on SDS-PAGE. MAP2A and MAP2B have been known to be heat stable, which is rather unique considering the high molecular weight of these proteins. MAP2B encodes proteins of 1828 amino acid residues;

MAP2A is a splice variant having additional exon of 83 amino acid residues in the middle of the molecule. Rotary-shadowing electron microscopy revealed that MAP2A and MAP2B are highly elongated, flexible molecules of ~100 nm in length. Subsequent study revealed that there is an additional low-molecular-weight form, MAP2C, which is ~70 kDa on SDS-PAGE. In MAP2C, the N- and C-terminal ends are joined, resulting in the protein of 467 amino acid residues. The unique characteristic of MAP2 is that they have binding domain for the regulatory subunit of type II cyclic AMP-dependent kinase on the N terminus. The C-terminal portion of the MAP2 forms the microtubule-binding domain (Table 1 and Figure 3). The sequence of this region does not have homology to MAP1, but it has unique imperfect tandem repeats of 31–32 amino acids; similar repeats of 18 amino acids joined by less-conserved, variable ‘spacers’ of 13–14 amino acids. These repeats bind to the C-terminal ends of tubulin. These imperfect tandem repeats are also used in the microtubule-

Figure 3 Schematic diagram of representative MAPs. Domain structures of MAP1A, MAP1B, MAP2A, MAP2B, MAP2C, tau, MAP4, and BPAG1-a are shown. Numbers of amino acids of representative molecules are shown on the right. MAP1A and MAP1B have a microtubule-binding domain on the N-terminal portion, which is domain enriched in the positively charged amino acids and contains the short motif (KKEX), repeated 11 and 21 times in MAP1A and MAP1B, respectively. C-terminal portion serves as a projection domain. MAP2A, MAP2B, MAP2C, tau, and MAP4 have a microtubule-binding domain on the C-terminal portion, which is a unique imperfect tandem of three or four basic repeats of 31–32 amino acids, similar repeats of 18 amino acids joined by less conserved, variable ‘spacer’ of 13–14 amino acids, and is quite well preserved among these MAPs. Molecules with three repeats are depicted in the drawing. BPAG1-a, one of the new MAPs, has actin-binding domain, plakin domain, spectrin-repeat-containing rod domain, GAR domain, and GSR domain. The GAR and the GSR domain together constitute the microtubule-binding domain in BPAG1-a as well as in MACF. In plakin, which is not depicted here, GAR domain is missing and GSR domain at the C-terminal portion can associate with microtubules. Not drawn to scale.

binding domain of tau and MAP4, which also reside in the C-terminal part of the molecule. Each molecule has three or four repeats. The central portion of the MAP2A and MAP2B molecule corresponds to the extended arm. Lacking this arm portion, MAP2C is revealed as filamentous molecule ~50 nm in length by the rotary-shadowing electron microscopy.

MAP2 is almost exclusively expressed in neurons. Importantly, MAP2A and MAP2B are specifically localized to the dendrites. It is often used as markers for the dendrites. There is a developmental regulation of MAP2 expression. MAP2C is expressed in juvenile neuron; it is found in cell bodies, dendrites, and axons. MAP2A is expressed in the adult, and MAP2B is expressed throughout the developmental stage.

Tau

Tau was the first MAP purified from the brain. It is heat stable, consists of several bands of 55–65 kDa on SDS-PAGE. It is now known that tau consists of six isoforms (ranging from 352 to 441 amino acid residues), which are splice variants of single tau gene. In the C-terminal half of the molecule, tau has three or four tandem repeats of 31 or 32 amino acids, as described above, which serves as the microtubule-binding domain (Table 1 and Figure 3). In rotary-shadowing electron microscopy, tau forms filaments of ~50 nm in length. Tau

forms ~20 nm short filamentous structures associated with microtubules. It is known that in the peripheral nervous system, additional isoform of 110 kDa is expressed. However, this isoform is less well characterized.

There is a developmental regulation of expression of tau isoforms. In the juvenile brain, only the three repeat isoforms are expressed, and in the adult brain, tau isoforms with both three and four repeats are expressed. Tau is posttranslationally modified by phosphorylation. A part of the heterogeneity of the tau bands on the SDS-PAGE results from phosphorylation. When antibodies that recognize all tau isoforms are used, tau is predominantly localized in the axon, with some expression in cell bodies and dendrites.

MAP4

Although MAP1, MAP2, and tau are rather abundantly expressed in the nervous system, their expression outside the nervous system is limited. MAP4 is a major MAP found outside the nervous system. It is a protein of 210 kDa on SDS-PAGE. MAP4 encodes protein of 1072 amino acid residues. It is composed of an N-terminal projection domain and a C-terminal microtubule-binding region, which has homology to the microtubule-binding domain of tau and MAP2 (Table 1 and Figure 3).

Control of Microtubule Dynamics

Microtubules are dynamic and unstable. By binding along the sides of the microtubules, MAPs control microtubule dynamics *in vitro* and *in vivo*. Many MAPs, including classical MAPs, stabilize microtubules. Classical MAPs were usually expressed predominantly in the nervous system. Microtubules in the neuron are usually much more stable than those in most interphase cells. Therefore, it is not surprising that one important function of classical MAPs is the stabilization of microtubules against disassembly. As described above, tau, MAP2, and MAP4 share conserved C-terminal three or four pseudorepeats, which serves as microtubule-binding domain. In tau, it is shown that one of these repeats bind to the tubulin C-terminal end, and other repeats bind to another internal site of tubulin. Therefore, these tandem repeats are likely to bind to microtubule in such a way to cross-link adjacent tubulin subunits and stabilize microtubules against disassembly. These bindings are controlled by phosphorylation. Both tau and MAP2 have many residues, which can be phosphorylated.

There are other modes of regulation of microtubule dynamics by MAPs. Microtubule is usually disassembled in cold temperatures. Stable tubule-only polypeptide (STOP) is a MAP known to stabilize microtubules against cold temperatures. A few MAPs are also known to destabilize microtubules, including katanin, Op18, and stathmin. In addition to structural MAPs, some of the kinesin superfamily proteins belonging to KIF2 class also destabilize microtubules.

Bundling of Microtubules: MAPs and Neurite Outgrowth

Neuron extends axon and dendrites from the cell body. In the axon and dendrites, microtubules run in parallel, in

Figure 4 Microtubule bundle formation in fibroblasts transfected with tau cDNA. Immunofluorescence using anti-tubulin antibody. Long processes are formed and microtubule bundles extend into the processes. Upper right corner is the immunofluorescence of nontransfected control fibroblasts stained with antitubulin antibody. Microtubules radiate in various direction from the microtubule-organizing center near the nucleus. Scale = 10 μ m. Reproduced from Kanai Y, Takemura R, Oshima T, et al. (1989) Expression of multiple tau isoforms and microtubule bundle formation in fibroblasts transfected with a single tau cDNA. *Journal of Cell Biology* 109: 1173–1184, with permission of the Rockefeller University Press.

longitudinal array. In the quick-freeze, deep-etch electron microscopy, it can be shown that microtubules are highly cross-linked by meshwork of fine filamentous structures in axons and dendrites (Figures 1 and 2). MAPs form these cross-linkers. Moreover, MAPs induce microtubule bundle formation and outgrowth of processes from the cell. When classical MAPs are transfected and overexpressed in the cells, such as fibroblast or Sf9 cells, unusual microtubule bundles are formed, and long processes very much like neurites can be induced (Figures 4 and 5).

In addition, MAPs determine the spacing between neighboring microtubules to be axon like or dendrite like. Namely, MAPs expressed in the axon, such as tau and MAP2C, produce microtubule bundles similar to those seen in the axon (wall-to-wall distance of neighboring microtubules, ~ 20 nm), and MAPs expressed in the dendrites, such as MAP2A and MAP2B, produce microtubule bundles similar to those seen in the dendrites (wall-to-wall distance of neighboring microtubules, ~ 65 nm) (Figure 5). Therefore, in addition to the stabilization of microtubules, projection domains of MAPs induce microtubule bundle formation, induce process outgrowth, and determine the spacing between microtubules.

Analysis of Transgenic and Knockout Mice: Relation of MAPs to Neurodegenerative Diseases

Recently, genetically altered mice gave some insights into the role of individual MAPs *in vivo*. In general, lack of MAP

Figure 5 Cross-section electron micrographs of processes induced by transfection of MAP2 (a), MAP2C (b), and tau (c) into Sf9 cells. Each MAP2 forms microtubule bundles, but the organization is different. When MAP2 is transfected, wall-to-wall distance between nearest adjacent microtubules is ~ 65 nm, which is similar to the microtubule organization of Purkinje cell dendrite in the cerebellum (d). By contrast, when MAP2C or tau are transfected, the distance between microtubules is ~ 20 nm, which is similar to the microtubule organization of large myelinated axons in the spinal cord (inside the circle in (e)) or parallel fiber axons in the cerebellum (f). Reproduced from Chen J, Kanai Y, Cowan NJ, and Hirokawa N (1992) Projection domains of MAP2 and tau determine spacings between microtubules in dendrites and axons. *Nature* 360: 674–677, with permission of Nature Publishing Group.

produces the expected effect, but the overall effect is rather limited. This implies that there is certain overlap in the function of MAPs. In fact, when the double knockout mice were formed in the combination of two MAPs, the expected effect is much more severely observed. For example, in *tau*^{-/-} mice, an effect on the microtubule stabilization and bundle formation in the axon was observed, but the effect is evident mainly in the small caliber axon. Likewise, in *MAP2*^{-/-} mice, an effect on microtubule organization in dendrite is evident, but the effect is somewhat limited. However, when both tau and MAP1B, or both MAP1B and MAP2 are deleted, impaired microtubule bundle formation and outgrowth of axon or dendrite was markedly observed.

Tau has been implicated in the pathogenesis of certain cognitive neurodegenerative diseases. The diseases are sometimes grouped as tauopathies, which comprise a heterogeneous group of age-dependent cognitive disorders, including Alzheimer's disease. In these diseases, abnormally hyperphosphorylated tau forms filamentous aggregates within the cell. The aggregates do not contain microtubules, and the formation of aggregates is independent of microtubules. There is a loss of neurons in the affected brain area. In 1998, tau gene mutations were identified in patients with dementia and parkinsonism linked to chromosome 17 (FTDP-17). Transgenic mice with these mutations have been developed for an analysis.

New MAPs

Recently, a family of proteins of a very high molecular weight, plakin family, has been identified as cross-linker proteins that connect different cytoskeletal filaments. Some of the members, such as plectin, Bullous pemphigoid antigen 1 (BPAG1), and microtubule-actin cross-linking factor (MACF), have microtubule-binding domain, and they are likely to cross-link microtubule to intermediate filaments, or actin filaments. Microtubule-binding domain used in the plakin family proteins are of two kinds: Gas2-related (GAR) domain in BPAG1 and MACF; and glycine-serine-arginine (GSR) domain in plakin,

BPAG1, and MACF (Figure 3). That these new cross-linkers play an important physiological role is suggested by the fact that mutations in these proteins cause neurological defects *in vivo*. For example, mutations in BPAG1 cause degeneration of sensory neurons, and mutations in MACF cause deficits in axon outgrowth and dendritic sprouting.

Mitochondria in Myocardial Ischemia

F Di Lisa, University of Padua, Padua, Italy

Glossary

Diastole Period of relaxation of the heart muscle, accompanied by the filling of the chambers with blood that is followed by systole.

Heart failure A condition resulting from a variety of cardiac diseases associated with an inadequate pumping function of the heart.

Infarction Cellular death caused by a prolonged obstruction of the inflow of arterial blood that is generally caused by the thrombotic occlusion of an atheromatous lesion.

Ischemia Deficient supply of blood to a body part (as the heart or brain) that is due to obstruction of the inflow of arterial blood (i.e., coronary arteries in the case of myocardial ischemia).

Ischemic postconditioning An intrinsic process whereby brief periods of ischemia alternating with brief periods

of re-flow applied at the onset of reperfusion following sustained ischemia reduces myocardial infarct size.

Ischemic preconditioning An intrinsic process whereby repeated short episodes of ischemia alternating with brief periods of re-flow protect the myocardium against a subsequent prolonged ischemic insult that would be otherwise lethal.

Myocyte The type of cell found in muscles.

Reperfusion Restoration of the flow of blood to a previously ischemic tissue or organ.

Sarcomere The basic unit of a myocyte composed of long, fibrous proteins, mostly actin and myosin, that slide past each other when the muscles contract and relax.

Systole Period of contraction of the ventricles of the heart that causes the ejection of blood into the aorta and pulmonary trunk.

In the heart, oxygen supply is generally reduced by coronary obstruction resulting in a critical reduction of flow (ischemia). In the affected region deprived of oxygen, drastic changes of metabolism and lack of adequate washout determine an abnormal accumulation of ions and metabolites. The readmission of coronary flow (post-ischemic reperfusion), which is obviously necessary for the maintenance of cardiomyocyte viability, is beneficial only after short periods of ischemia. When the duration of ischemia is prolonged, reperfusion exacerbates functional and structural alterations induced by ischemia creating conditions that are hardly compatible with cell survival. The following paragraphs are focused on the alterations in energy-linked functions of mitochondria that are involved in cardiomyocyte death during ischemia and reperfusion.

Ischemia and Energy Metabolism

At a cellular level, the onset of ischemia is determined by an insufficient availability of oxygen for mitochondrial oxidations. As a consequence of the reduced or absent oxidative phosphorylation, intracellular creatine phosphate is rapidly depleted with a concomitant rise in P_i , both factors stimulating glycolysis and lactate formation. The accumulation of lactate and the hydrolysis of adenosine triphosphate (ATP) decrease intracellular pH. During the early phase of ischemia, the failure of contraction and the rigor contracture, which are the most relevant changes in myocardial function, are caused by intracellular acidosis and severe reduction in ATP content respectively (Figure 1). Besides these relevant functional changes, several cellular activities are modified by the fall in pH and ATP content, including the inhibition of glycolysis

which is observed under conditions of severe ischemia. A low pH and the accumulation of lactate decrease the activity of both phosphofructokinase (PFK) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH). In addition, the fall in ATP is associated with membrane binding and inactivation of PFK. Thus, the failure in mitochondrial ATP production, which initially stimulates glycogen breakdown and glycolysis, is followed by the inhibition of glycolysis that is the only alternative pathway for ATP synthesis in anaerobic cells.

Despite the arrest of the respiratory chain, the mitochondrial membrane potential ($\Delta\psi_m$) is not immediately collapsed at the onset of ischemia. In fact, $\Delta\psi_m$ is maintained by the inverse operation of the F₀F₁ adenosine triphosphatase (ATPase) that uses ATP generated by glycolysis. Therefore, during ischemia not only do mitochondria cease to be the major ATP producers of the cell, but they can also become its major consumers.

Information from Isolated Cardiomyocytes

The multifaceted relationship between ischemia-induced mitochondrial dysfunction and alterations of cardiac structure and function have been elucidated by studies in isolated cardiomyocytes. These cells show a rod-shaped morphology and do not display spontaneous contractions. Rhythmic contractions can be evoked by electrical stimulation. Under de-energizing conditions, rod-shaped myocytes can either change into square forms (rigor state or contracture) or hypercontract into rounded dysfunctional forms in which the typical sarcomeric striature is no longer distinguishable (hypercontracture).

At the single cell level, hypercontracture is the paradigm of irreversible damage and is considered equivalent to the abrupt rise in diastolic pressure in the absence of contractile activity

Figure 1 Relationships between mitochondrial dysfunction and the characteristic sequence of cardiac alterations occurring during ischemia and reperfusion. The upper panel is a typical example of the changes in left ventricular pressure (LVP) that are observed in isolated and perfused rodent hearts subjected to prolonged ischemia (60 min) followed by reperfusion. Pi, inorganic phosphate.

which is observed in the intact heart when reperfusion takes place after a prolonged ischemia. However, in the intact heart, irreversible damage is characterized by the loss of cell membrane integrity, easily demonstrated by the release of intracellular proteins in the coronary effluent (Figure 1). Conversely, hypercontracted myocytes often retain the integrity of sarcolemma, as demonstrated by the retention of small molecules such as intracellularly trapped fluorescent probes. The difference between single cells and intact hearts is likely explained by the lack of cell attachments. The same morphological distortion which determines the hypercontracture in isolated myocytes could probably cause the rupture of the sarcolemma in the intact heart by tearing off adjacent myocytes.

Mitochondria in the Transition from Reversible to Irreversible Injury

Prolongation of ischemia (i.e., more than 20 min of no-flow ischemia in perfused hearts) leads myocytes to a point of no return beyond which even readmission of oxygen fails to rescue cell viability.

Myocardial tissue exhibits a peculiar transition from reversible to irreversible damage. In every cell type, the lack of ATP production and a severe decrease of its content result in a slow degenerative process which eventuates in the loss of plasma membrane integrity with release of intracellular components. Thus, if the initial pathological stimulus (i.e., lack of oxygen) is not removed, the inhibition or the alteration of mitochondrial

function results in cell death. In addition to this common mode of cell death, which occurs gradually, the myocardium exhibits a peculiar transition to irreversible injury, which occurs suddenly when oxygen supply is re-established after a prolonged period of ischemia. In this case, the uncontrolled hypercontracture of myofilaments is associated with a rapid increase in cell membrane permeability followed by the release of intracellular constituents.

The sudden changes produced by reperfusion on myocardial viability are concomitant with massive accumulation of calcium within the mitochondrial matrix. This seminal finding that highlighted the role of intracellular Ca²⁺ overload in myocardial pathology indicates that the rapid transition toward cell death requires a coupled mitochondrial respiration. In fact, respiratory chain inhibition or uncoupling of oxidative phosphorylation blunts enzyme release occurring at the onset of post-ischemic reperfusion. Therefore, oxidative phosphorylation not only is essential for cell recovery, but can also contribute to the processes causing cell necrosis.

Two major questions arise from these seminal findings: (1) Why is mitochondrial function required to cause hypercontracture or tissue injury upon reperfusion? (2) Which are the causes of mitochondrial dysfunction?

The apparent paradox linking mitochondrial function with cell death is related to the different ATP requirements of contraction and relaxation at the myofilament level. A suboptimal mitochondrial function could produce low levels of ATP which, in the presence of even a modest rise in [Ca²⁺]_i, might be sufficient for the formation of rigor bonds but not for the

relaxation process, resulting in myofilament hypercontracture. Supporting this concept, at reperfusion hypercontracture is abrogated not only by preventing oxidative phosphorylation, but also by inhibiting myosin ATPase.

Regarding the causes of mitochondrial dysfunction, upon reperfusion mitochondria are exposed to high levels of Ca^{2+} that is increased in the cytosol due to both the failure of Ca^{2+} ATPases and uptake through the sarcolemma $\text{Na}^+/\text{Ca}^{2+}$ exchanger. Since mitochondrial Ca^{2+} uptake and ATP synthesis utilize the same driving force, namely the $\Delta\psi_{\text{m}}$, mitochondrial Ca^{2+} accumulation results inevitably in a significant decrease in ATP formation. In addition and importantly, as detailed in the following paragraphs, the rise in intramitochondrial $[\text{Ca}^{2+}]$ ($[\text{Ca}^{2+}]_{\text{m}}$) promotes opening of the mitochondrial permeability transition pore (PTP) and is associated with increased formation of reactive oxygen species (ROS). Eventually a vicious cycle is generated whereby high $[\text{Ca}^{2+}]_{\text{m}}$, PTP opening and ROS formation hamper mitochondrial function jeopardizing the maintenance of cell viability.

Although ROS can be generated at several intracellular and extracellular sites, in cardiac myocytes the major source is represented by mitochondria that are on the other hand a prominent target of oxidative stress. A slight generation of ROS has been observed in ischemic or hypoxic cardiomyocytes, especially in isolated cells. However, a major burst in ROS formation occurs at the onset of reperfusion providing a significant contribution to the rapid evolution toward cell death. Alterations of respiratory chain induced by ischemia are likely to contribute largely to mitochondrial ROS generation during reperfusion. However, it must be pointed out that besides respiratory chain complexes, especially I and III, three other systems have been described for ROS generation in mitochondria, namely 'monoamine oxidases' (MAOs), p66^{Shc} , and NADPH oxidase 4 (NOX4). While MAO are located to the outer mitochondrial membrane (OMM), p66^{Shc} is translocated from cytosol into the intermembrane space where it catalyzes electron transfer from cytochrome *c* to oxygen-generating H_2O_2 . The recent addition of NOX 4 to the list of mitochondrial systems generating ROS is more controversial, since also a localization to endo/sarcoplasmic reticulum has been reported. However, due to close vicinity, ROS formed at endo/sarcoplasmic reticulum would easily attack mitochondrial components. Interestingly, pharmacological inhibition or genetic deletion of these ROS-generating systems results in a significant decrease of reperfusion-induced loss of cardiomyocyte viability. Additional studies are required to elucidate the relationships among the mitochondrial systems that generate ROS especially during post-ischemic reperfusion.

The Mitochondrial PTP as a Target of Ischemic Injury and Pharmacological Interventions

A general consensus exists that the PTP is a major factor in determining cardiomyocyte death, and that PTP inhibition affords significant cardioprotection against the ischemia/reperfusion injury, a concept that has been successfully translated to clinical settings.

As detailed elsewhere in the encyclopedia, major functional and structural changes are induced in mitochondria, and

consequently to the whole cell, by PTP opening that causes a sudden increase in the permeability (i.e., permeability transition) of the inner mitochondrial membrane (IMM) to solutes with molecular masses up to 1500 Da. The PTP can be defined as a high-conductance channel located in the IMM. Its opening is favored by a decrease in mitochondrial membrane potential, elevation in matrix $[\text{Ca}^{2+}]$, and oxidative stress.

Among the many proteins described in PTP regulation, major attention has focused on the matrix protein cyclophilin (CyP) D due to its importance in pharmacological control of PTP opening and to the pivotal information provided by its genetic deletion. PTP opening is facilitated by binding of CyPD to the IMM in a process modulated by Ca^{2+} , Pi, and ROS. Notably, CyPD binding to the IMM is prevented by cyclosporine A (CsA) and by other molecules interacting with CyPD that are usually described as PTP inhibitors. However, since increasing $[\text{Ca}^{2+}]$ results in PTP opening even in the presence of these molecules, PTP desensitization describes better than PTP inhibition the effect of this family of compounds, a concept that also applies to mitochondria devoid of CyPD.

The relationship between CyPD and PTP has initially been demonstrated by pharmacology through the use of CsA, and then corroborated by using other CyPD ligands. However, conclusive evidence for a regulatory role of CyPD was provided by genetic studies demonstrating that the propensity of the PTP to open is reduced in mitochondria devoid of CyPD, while susceptibility to PTP opening and to cell death is increased when CyPD is overexpressed.

Although PTP structure is still elusive and its modulation is far from having been conclusively elucidated, the relationship between PTP opening and cell death is supported by a large body of evidence, especially in the field of acute myocardial ischemia and reperfusion. PTP opening is causally linked to the loss of cell viability as demonstrated by the reduction in infarct size obtained when PTP opening is counteracted by pharmacological inhibitors or by genetic ablation of CyPD.

PTP opening favors ATP depletion, deregulation of cellular Ca^{2+} homeostasis, and oxidative stress, all of which synergize in jeopardizing cell survival. The sequence of events can be summarized as follows. PTP opening determines an immediate collapse of $\Delta\psi_{\text{m}}$ that is followed by ATP depletion. When opening is prolonged, the initial uncoupling-like effect is rapidly followed by respiratory inhibition caused by loss of pyridine nucleotides and of cytochrome *c*. This latter event can be contributed by the rupture of the OMM that follows PTP-dependent matrix swelling, or by making more cytochrome *c* available for release through cristae junction widening followed by release through Bax/Bak channels through an otherwise intact OMM. The resulting inhibition of electron flow might explain the increased ROS formation induced by PTP opening. Since the latter event is favored by ROS, a vicious cycle of injury amplification is likely to be established, especially at the onset of reperfusion.

Regarding ischemia/reperfusion injury, during ischemia the build-up of factors favoring PTP opening (e.g., depolarization and increased Ca^{2+} and Pi matrix levels) is balanced by the presence of PTP antagonists (i.e., intracellular acidosis, high levels of Mg^{2+} , and adenosine diphosphate (ADP)), which may prevail and prevent PTP opening. Conversely, upon reperfusion, the recovery of pH together with a burst in ROS

formation in the presence of high-matrix concentrations of Ca^{2+} and Pi creates optimal conditions for PTP opening in spite of the antagonizing effect of $\Delta\psi_m$ recovery. The concept that PTP is more likely to open upon reperfusion is supported by findings obtained in intact hearts using direct methods for PTP assessment. Notably, the promoting effect of Ca^{2+} is also due to indirect effects that add to its direct action on mitochondria. For instance, arachidonic acid released from phospholipids through the action of Ca^{2+} -dependent phospholipase A_2 and the activation of the Ca^{2+} -dependent proteinase calpain are likely to further facilitate PTP opening.

CsA-dependent cardioprotection is likely to involve also mechanisms other than CyPD inhibition. For instance, the CsA/CyPA complex binds to and inhibits the cytosolic phosphatase calcineurin preventing mitochondrial fragmentation. In fact, due to its Ca^{2+} -dependent phosphatase activity, calcineurin promotes the intracellular redistribution of dynamin-related protein 1 (Drp1) that only in its dephosphorylated form translocates to mitochondria causing their fragmentation. The relevance of this process in myocardial ischemia is highlighted by recent reports showing that genetic or pharmacological inhibition of Drp1 affords a significant protection against various injury conditions including post-ischemic reperfusion. Therefore, PTP opening might be the consequence and not only the cause of derangements in mitochondrial structure and function.

Mitochondria and Endogenous Self-Defenses Triggered by Conditioning Stimuli

Endogenous defense mechanisms are triggered by conditioning stimuli to maintain cardiomyocyte viability during ischemia or reperfusion. The term 'ischemic preconditioning' (IPC) describes the process whereby repeated short episodes of ischemia and reperfusion protect from a subsequent prolonged ischemia. The deleterious effects of post-ischemic reperfusion have been shown to be limited also by performing a series of very short periods of ischemia and reperfusion at the time of reperfusion. This maneuver is termed 'ischemic post-conditioning' (IPoC) and has received great attention as a promising protective strategy in clinical settings.

Both IPC and IPoC have been related to PTP based upon the following major lines of evidence: (1) IPC results in a decreased occurrence of PTP opening during post-ischemic reperfusion; (2) IPC and IPoC reduce PTP susceptibility in mitochondria isolated during reperfusion; and (3) cardioprotection by IPC and IPoC is similar to that obtained using compounds or interventions that decrease PTP opening.

The notion that the PTP contributes to mediate IPC has been corroborated by observations suggesting that CyPD inhibition or deletion abolishes the cardioprotective effects of IPC itself. This apparent paradox reminds of, and fits well with, the concept that a slight increase in ROS formation during the preconditioning phase prevents the large accumulation in ROS induced by reperfusion, and thus results in maintenance of myocardial viability.

The mechanisms by which IPC and/or IPoC affect mitochondrial function and structure, as well as PTP opening, have not yet been elucidated. Evidence has been provided that IPC/

IPoC-induced changes in signaling pathways are related to the increased resistance of mitochondria to ischemia/reperfusion (I/R) injury. For instance, IPC-induced inactivation of glycogen synthase kinase 3β (GSK- 3β) results in PTP inhibition. The constitutively active GSK- 3β would be inactivated by phosphorylation at Ser⁹ catalyzed by upstream protein kinases. These have been grouped under the acronyms of RISK (reperfusion injury salvage kinase), including phosphatidylinositol-3-OH kinase-Akt and ERK 1/2, and SAFE (survivor-activating factor enhancement) describing the activation of the cytokine tumor necrosis factor α and signal transducer and activator of transcription-3 (STAT-3). In addition, activation of cyclic guanosine monophosphate (GMP)-dependent protein kinase (PKG), cyclic adenosine monophosphate (AMP)-dependent protein kinase (PKA), and Ca^{2+} -dependent protein kinase ϵ (PKC ϵ) have been reported to contribute to the maintenance of mitochondrial function in hearts undergoing I/R, whereas PKC δ (together with GSK- 3β) appears to facilitate mitochondrial dysfunction.

Despite the large amount of data supporting the relevance of (de)phosphorylation processes in IPC-mediated mitochondrial and cardiomyocytes protection, the field is still controversial. First, the mechanisms linking signaling pathways activated in the cytosol with energy-linked process occurring within the IMM are far from being elucidated. Candidate (de) phosphorylation reactions occurring at the level of the OMM might involve the voltage-dependent anion channel (VDAC), thus affecting adenine nucleotide traffic between mitochondria and cytosol, and/or binding of the anti-apoptotic protein Bcl-2. A PTP-regulatory role has been proposed also for IPC-induced opening of the mitochondrial K_{ATP} channel by PKC ϵ , which may cause a slight increase in H_2O_2 formation eventually causing PTP inhibition. Second, in some experimental models activation of the RISK pathway appears to be independent of any protective effects. It has been suggested that rather than causing direct and immediate modifications in protein (de)phosphorylation, IPC reduces the extent of oxidative stress during ischemia and reperfusion. Although the burst in ROS formation occurring during reperfusion is clearly reduced in IPC-treated cardiomyocytes, the mechanism by which IPC or IPoC might affect oxidative stress is yet ill defined.

Mitochondrial Auto-Antibodies

H Baum, King's College London, London, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

CD4⁺-T cell T-lymphocyte, with a receptor recognizing a specific short peptide, derived from an antigen and presented by an antigen-presenting cell and, thereafter, primed to help B-cells that also present that peptide to secrete antibodies against the antigen.

Epitope The specific target recognized by a T-cell or antibody.

Immunofluorescence A technique for detecting antibodies that bind to specific structures on tissue sections, by

treatment with a fluorescently labeled, anti-immunoglobulin antibody.

Lipoyl residue The amide of 6,8-dithio-octanoic acid, the oxidized, disulfide form of which is reductively acylated in the catalytic cycle of the 2-oxoacid dehydrogenase complexes.

Molecular mimicry Similarity in structure, either accidental or evolutionarily selected, between two antigens, leading to immunological cross-reactivity.

Detection of Mitochondrial Auto-Antibodies

Anti-mitochondrial antibodies (AMAs) have been detected by immunofluorescence (IFL) (where they are visualized as bright granular staining in cell types with high mitochondrial content), or by applying complement fixation tests (CFTs), enzyme-linked immunosorbent assays (ELISAs), Line or Dot-blot immunoassays, or Western immunoblotting (IB) to tissue extracts, purified subcellular constituents, or specific, recombinant mitochondrial species. Proof that mitochondria were the target of antibodies detected by such methods was provided in early studies, such as the landmark paper of Walker et al. by the specific absorption of serum reactivity using preparations of mitochondria. It was subsequently recognized that AMAs recognizing different mitochondrial antigens might characterize different clinical conditions. The molecular identity of many, but not all, of these antigens is now established. Not all of these AMAs are detectable by all of the above methodologies. The preferred test in some general diagnostic laboratories is IFL on a composite substrate of rodent tissues, complemented by ELISAs when appropriate. In other laboratories, particularly when primary biliary cirrhosis (PBC) is the concern, the preferred test is ELISA. In the research laboratory, and where specific AMAs are under investigation, the preferred assays are ELISAs and IB, using purified or recombinant antigens, or synthetic peptides.

The M-Classification of AMAs

In the early 1980s, an arbitrary classification of AMAs, as anti-M1-9, was developed, mainly by Berg's group in Tübingen, on the basis of patterns of IFL and/or properties of target antigens as determined by various assay procedures. It is noteworthy that in all these cases, the AMAs are not species specific. Although this M-classification is now more or less obsolete, and does not include all known mitochondrial targets for AMAs, it is still a helpful convention for listing reactivities (Table 1).

Anti-M1 AMAs and Cardiolipin

The M1 pattern of IFL is exhibited exclusively with sera of patients with untreated secondary syphilis. The reaction is abolished completely by absorption of sera with cardiolipin, the characteristic phospholipid of the mitochondrial inner membrane. However, the simple conclusion that anti-M1 antibodies are specific for cardiolipin is complicated by another observation. The earlier diagnostic test for syphilis, the Wasserman reaction, is based on CFTs against cardiolipin. However, not all sera positive in this test show an M1 pattern of IFL. Moreover, Wasserman-positive sera that are negative for M1 give a strongly positive ELISA reaction against purified cardiolipin, whereas anti-M1 AMAs are scarcely detectable by ELISAs using purified cardiolipin, while they react strongly in ELISAs against submitochondrial particles. Interestingly, M1-negative, Wasserman-positive sera are frequently false positives for syphilis and may instead reflect collagen disorders such as systemic lupus erythematosus (SLE). It seems likely that these anomalies reflect antibodies to different epitopes in cardiolipin, the different assay systems exposing different conformations of the same molecule. (Indeed some of the anti-cardiolipin antibodies in M1-negative sera of SLE patients may be detected as antibodies against nucleic acids, cross-reactivity arising by virtue of the similarity between the glycerol phosphate arrays in cardiolipin arrays and the ribose phosphate backbone of nucleic acids.) Anti-M1 AMAs probably recognize a more native form of the lipid, as it exists in the intact mitochondrial membrane (and may arise from immunological cross-reactivity with a membrane constituent of the agent of syphilis, *Treponema pallidum*).

Anti-M2 AMAs

The most important mitochondrial auto-antibodies, anti-M2 AMAs, exhibit a characteristic pattern of IFL and were initially defined both by their disease specificity and by properties of the antigen that they recognized. This was shown to be trypsin sensitive and associated with (but detachable from) the inner surface of the inner membrane of all mitochondria tested, from

Table 1 The M-classification of specificities of mitochondrial auto-antibodies

Antigen	Occurrence of auto-antibodies
M1	Secondary syphilis
M2	PBC
M3	Phenopyrazone-induced pseudolupus syndrome
M4	PBC (prognostic indicator?); other chronic liver diseases
M5	Subgroup of systemic lupus; anti-phospholipid syndrome
M6	Iproniazid-induced hepatitis
M7	Cardiomyopathies
M8	PBC (prognostic indicator?)
M9 ^a	PBC (prognostic indicator?)

^aIn fact this antigenic specificity is not mitochondrial (see text).

human to fungal. Anti-M2 antibodies were also shown to cross-react with several bacteria, anti-mitochondrial activity, for example, being absorbed out of PBC sera by *Escherichia coli*.

Association with primary biliary cirrhosis

PBC is a chronic, cholestatic liver disease, predominantly affecting middle-aged women. It is characterized by spontaneous inflammatory damage to the epithelial cells of the bile duct (BEC). While the clinical presentation and disease progression are variable, and the disease may be virtually asymptomatic for many years, the end stage is cirrhotic liver failure, and the disease is the second most frequent reason for liver transplantation in the developed world. Although the most clinically significant pathology relates to the liver, PBC is actually a multi-system disorder and may feature lachrymal salivary and pancreatic hyposecretion. The paper by Walker, referred to earlier, and many subsequent studies, demonstrated clearly that PBC is characterized by high and persistent titers of AMAs of a kind not seen in normal subjects or other diseases. Since the description of this close association, the detection of this class of AMAs, designated as anti-M2, has acted as a powerful diagnostic tool. Anti-M2 antibodies (both IgG and IgM) are found in up to 98% of PBC patients, the precise figure depending on the sensitivity of the assay used. Interestingly, these AMAs are not restricted to serum, being found in the bile, saliva, and urine of patients with PBC. Moreover, anti-M2 AMAs have turned out to be predictors for the disease; asymptomatic subjects, accidentally having been identified as being positive for anti-M2 AMAs, are frequently found to develop the disease subsequently.

Identity of M2 antigens

Western IB soon revealed that M2 actually consists of a family of up to seven co-purifying peptides of differing molecular weight, encompassing a spectrum from around 75 to 36 kDa. Different PBC sera demonstrated different patterns of reactivity against these (see Table 2), but virtually all recognized a predominant peptide that was eventually identified as being the E2 component (dihydrolipoamide acetyltransferase) of the pyruvate dehydrogenase complex. Thereafter, it soon became clear that the other M2 antigens were also constituents of one or other of the 2-oxo-acid dehydrogenase multienzyme complexes (OADCs): pyruvate, 2-oxoglutarate, and branched-chain 2-oxo acid dehydrogenase complexes (PDC, OGDC, and BCOADC, respectively). Each of the three

Table 2 Frequency of occurrence of anti-M2 AMA to specific antigens in PBC

Complex	Subunit	Apparent M_r (kDa)	AMA-positive (%) ^a
PDC	E1 α	41	53
PDC	E1 β	34–36	4
PDC	E2	70–74	96
PDC	E3BP (X)	50–56	96
OGDC	E2	48–50	74
BCOADC	E1 α	46	50
BCOADC	E2	50–52	56
All	E2's		50
At least one	E2		98

complexes occupies a key position in energy metabolism in aerobic cells. Each consists of multiple copies of at least three enzymes (E1, E2, and E3), which are encoded by genes in the nucleus and separately imported into mitochondria for assembly into high-molecular-weight multimers localized to the matrix aspect of the inner membrane. The structural core of these complexes is provided by E2 (the acyltransferase), to which multiple copies of E1 (the decarboxylating dehydrogenase) and E3 (dihydrolipoamide dehydrogenase) are noncovalently bound. The E2 enzymes are notably homologous in structure as between different complexes and different species (e.g., there is 52% similarity in sequence as between rat PDC-E2 and OGDC-E2 of *E. coli*). E3 is common to all three complexes, whereas E1 and E2 are unique to each complex. PDC contains a fourth polypeptide with a structural role, the E3-binding protein (E3BP), once termed 'protein X'. This contains a lysine-linked lipate moiety, located in a domain that is strongly homologous to corresponding domains in PDC-E2.

In view of this latter homology, it is not surprising that all sera recognizing PDC-E2 also bind E3BP and that the antibodies to the two peptides are cross-reactive. The other members of the M2 family were shown to include the E2's of OGDC and BCOADC. However, notwithstanding the general similarity between the respective E2's, there seems only to be a limited degree of antibody cross-reactivity between them and only about 50% of PBC sera recognize all three. (On the other hand, AMAs against a particular E2 recognize that peptide in mitochondria of all species is being tested.) About half of all PBC sera also recognize the α -subunit of PDH-E1 (with the β -subunit being rarely recognized). Additionally, human auto-antibodies, specific for BCOADC-E1 α , were found, in a more recent study, in the sera of almost half of the PBC patients tested. A summary of frequency of occurrence of AMAs to individual members of the M2 family is given in Table 2. The E3 component, a common subunit of all three complexes, is not listed in the table. This is because, although specifically anti-mammalian E3 antibodies are found in PBC, these are in relatively low amount and are not totally disease specific.

Enzyme inhibition by anti-M2 AMAs

A notable characteristic of AMAs in PBC sera is their capacity to block the catalytic function of the 2-OAD multienzyme complexes *in vitro*. For example, sera with AMAs recognizing PDC-E2 rapidly inhibit PDC at dilutions of 1/500–1/5000, much of this inhibitory activity being removed by pre-

absorption of the sera with recombinant PDC-E2. Similarly, affinity-purified antibody against PDC-E1 α also specifically inhibits PDC reactivity.

Possible target for anti-M2 AMAs on bile duct cells

What may be a key fact relating to the occurrence and disease association of AMAs in PBC is the reactivity that has been observed of anti-M2 AMAs (and of selected monoclonal antibodies against PDC-E2) with some component at the surface of a subset of BEC in livers of PBC patients. Conflicting views have been that this antigen is an inappropriately localized component of PDC, or that it is a different molecule with a sequence similarity to a dominant B-cell epitope. What does seem clear is that susceptibility of BEC is not host specific, since PBC may recur in allogeneic-transplanted livers. What is also very significant is that PDC-E2 has more recently been shown to be uniquely conserved in BEC following apoptosis, with evidence that it remains accessible to the immune system within apoptotic blebs. However, it has yet to be unambiguously demonstrated that the pathogenetic focus of the disease is reactivity of AMA with PDC-E2 at the surface of BEC.

Cross-reactivity of anti-M2 AMAs against bacterial E2's

Early reports of cross-reactivity of PBC-specific AMAs against a variety of bacterial species were confirmed in studies of reactivity against individual microbial E2's of the three OADC complexes. (There is no homology between microbial and corresponding mitochondrial E1's; neither is there reactivity of E1-specific AMAs against bacteria.) Further evidence of cross-reactivity is that antibodies raised in rabbits, against bacterial mutants having fragile cell walls, were reported to react with a typical M2 pattern on IB against mitochondria. However, detailed absorption/elution and other studies have led to a current view that, while there is indeed some cross-reactivity between corresponding enzymes, PBC sera contain distinct sets of antibodies against mitochondrial and microbial OADCs, respectively.

Anti-M2 AMAs and chronic bacterial infection

In a study of women with asymptomatic recurrent bacteriuria, a majority of the patients were found to be weakly positive for antibodies to PDC-E2 by immunoblot, in the absence of evidence of liver disease. AMAs were also detected by ELISAs and IB in 43% of patients with active pulmonary tuberculosis and in patients with leprosy. However, it is not clear whether what is being detected in these cases are true AMAs or antibodies against corresponding microbial enzymes that are partially cross-reactive against mitochondrial peptides.

Epitopes recognized by anti-M2 AMAs

Most studies on B-cell epitopes in PBC have focused on the E2 antigens. Here, it is clear that the main immunogenic regions are the lipoyl domains. Short peptides (e.g., of around 20 residues in length) encompassing the lipoyl-binding site are rather weakly antigenic, and full immunological reactivity is only seen for much longer peptides. Thus, for PDC-E2, the 93-residue sequence, 128–221, of the inner lipoyl domain is required for maximal antibody binding. The outer lipoyl domain, although containing a highly homologous region around the lysine residue that is bound to lipoate, is only weakly antigenic. These and other findings suggest that the

overall epitopes are conformational ones, but centered on the lipoyl-binding sites. The strong homologies between these domains among the three OADCs, and between mitochondrial and microbial enzymes, may account for partial cross-reactivities, with extended flanking regions being responsible for specificity and full reactivity. There is some disagreement as to whether lipoyl residues themselves are necessary for full reactivity, but corresponding peptides not containing lipoate are undoubtedly antigenic.

Stimulus for anti-M2 AMAs production in PBC

There is good evidence that B-cell clones producing AMAs are maximally stimulated, and it is noteworthy that the dominant epitopes of the CD4⁺ T-cells, that provide the help for antibody production, are short peptides of the lipoyl-binding domain. (Similar peptides are also the dominant epitopes of the cytotoxic CD8⁺ T-cells that infiltrate the bile ducts in this disease.) What then is the antigenic drive in PBC? It cannot be a secondary response to tissue damage, since M2 AMAs are not detectable in many other destructive diseases of the liver.

As mentioned earlier, chronic microbial infection may be characterized by low titers of anti-M2 AMAs. There is also epidemiological evidence of association between recurrent urinary tract infection (UTI) and PBC. Moreover, UTI is particularly common in middle-aged women, the group in which PBC most commonly occurs. Therefore, it is suggested that the initial stimulus for an immune reaction directed specifically at the E2's of the OADCs (and E3BP of PDC) is chronic exposure, in the context of co-stimulatory signals (and probably a particular genetic background), to microbial peptides that share strong sequence similarities with the lipoyl-binding domains at the core of the dominant epitopes. Expansion of reactivity and specificity to incorporate the entire domain, and then also to recognize E1 subunits, would be by epitope spreading. Such microbial mimics might not necessarily be the homologous OADCs. A number of other bacterial and viral peptides have been identified with strong sequence similarities to the core peptidyl epitope of PDC-E2, and have been shown, by ELISAs, to react specifically with PBC sera, the antibodies being cross-reactive with that core peptide. In particular, it has recently been shown that the amino acid sequences of two proteins of the ubiquitous, free-living bacterium, *Novosphingobium aromaticivorans*, present high degrees of homology with the main human PDC-E2 autoepitope, and that reactivity of these proteins against all anti-PDC-E2 positive sera was exceptionally high.

A parallel scenario to microbial infection has recently been suggested as initiating the autoimmune process, and this is modification of lipoyl residues of E2's by environmental xenobiotics. The central role of the liver in xenobiotic metabolism would then be a rationale for the location of the disease.

One other important fact needs bearing in mind in any speculation about antigenic drive. Once it is established, it persists, even though there might no longer be any relic of the triggering process. Thus, even after liver transplantation, high titers of anti-M2 AMAs are still found.

Role of AMAs in the pathogenesis of PBC

Anti-M2 AMAs are so focused in specificity and so disease specific that it has to be assumed that they are relevant to

disease pathogenesis, but most workers have concluded that it is T-cells rather than the antibodies themselves that are the direct cause of tissue damage. For example, high titers of AMAs can be raised in experimental animals, for example, by immunization with recombinant human PDC-E2, with no evidence of liver damage even after a prolonged period, and only a minority of patients exhibit unambiguous recurrence of PBC following liver transplantation, despite the persistence of AMAs. However, in the former case, fine specificities of the AMAs may not be identical to those of the PBC-specific antibodies, and in the latter, immunosuppressive drugs may be protective. If the AMAs were to be directly cytotoxic, it might be by inhibition of mitochondrial function following uptake into BEC. Such uptake might be mediated by binding to the elusive antigen that might be the primary recognition target at the surface of BEC.

Anti-M3 AMAs and Pseudolupus Syndrome

Some time ago, it was recognized that there was an association between the taking of the drug phenopyrazone, for cardiovascular disease, and a disorder designated as pseudolupus syndrome (PLE). This syndrome was characterized by AMAs that could be demonstrated by IFL, CFTs, and ELISAs, but not by IB. The antigen, classified as M3, was shown to be associated with the outer mitochondrial membrane and was not organ specific. High titers of anti-M3 were detectable during the acute phase of the disease, but they declined on cessation of treatment with phenopyrazone, a drug that has since been withdrawn. No further cases of PLE have been reported, and the M3 antigen has not been further characterized. However, it has been speculated that it might be a drug-metabolizing enzyme such as monoamine oxidase (MAO), rendered immunogenic through tight binding to the drug.

Anti-M4 AMAs and Sulfite Oxidase

In addition to anti-M2, another complement-fixing antibody has been shown to be associated with PBC. The target antigen in this case, designated as M4, was found to co-purify with the outer mitochondrial membrane and be insensitive to trypsin. It was identified as being sulfite oxidase, an enzyme of the inter-membrane space, a precursor of which binds to the outer membrane. Sulfite oxidase in an evolutionarily highly conserved enzyme, also found in bacteria, but enzyme activity does not seem to be inhibited by M4-positive PBC sera. Nevertheless, recombinant sulfite oxidase was shown by ELISA and IB to react with around 5% of sera from patients with PBC.

The clinical significance of the detection of anti-M4 in addition to anti-M2 AMA is controversial. There have been claims that anti-M4 AMAs reflect a mixed-form pathology of PBC with histological features of chronic active hepatitis, and/or that their detection is an indicator of poorer prognosis toward the end stage of the disease. However, it is now clear that this reactivity is not specific for PBC, and is indeed characteristic of chronic liver disorders in general, with the highest reactivity being seen in primary sclerosing cholangitis.

Anti-M5 AMAs and Phospholipid

Mention has been made that false Wasserman-positive tests may reflect a different conformation of cardiolipin than that

recognized by the M1-positive, syphilis-specific pattern of IFL, and are frequently associated with SLE. Such false-positive reactions often correlate with a characteristic IFL pattern, designated as M5. This pattern is seen with both a subset of SLE and patients with antiphospholipid syndrome, characterized by thrombocytopenia and recurrent fetal loss. While anti-M5 reactivity may be absorbed out by inner mitochondrial membranes, no specific reactivities have been detected against any mitochondrial proteins, and it is concluded that M5 is some form of phospholipid, although the reactivity is not absorbed out by cardiolipin liposomes or cardiolipin-glycoprotein complexes.

Anti-M6 AMAs and Immuno-Allergic Hepatitis

Anti-M6 AMAs have been detected, by a characteristic pattern of IFL, in sera of patients who had developed acute hepatitis associated with taking the anti-depressive drug iproniazid. The M6 antigen could be detected by CFTs and ELISAs, was partially tissue specific (liver-kidney), and was associated with the inner membrane. The antigen has now been identified as monoamine oxidase B (MAO-B) and the activity of this enzyme against substrates such as tyramine is inhibited by these AMAs. As MAO-B is irreversibly inhibited by iproniazid, the stimulus for AMA production may arise from metabolite/enzyme haptenization as also suggested, above, in the case of anti-M3.

Anti-M7 AMAs and Flavoenzymes

Around 60% of patients with acute myocarditis and 30% of patients with cardiopathy of unknown etiology exhibit a class of AMAs designated as anti-M7. The antibodies in acute myocarditis are predominantly of the IgM class and disappear on recovery, while in chronic disease they are IgG and persist. Such antibodies are not seen in coronary artery conditions and have been considered as reflecting infective disease. The target antigen was originally reported as being heart specific and tightly associated with the inner mitochondrial membrane, but it is now recognized that this class of AMA is directed generally against flavoenzymes. Hence, in heart mitochondria a dominant target is the flavoprotein of succinate dehydrogenase, while in liver it includes sarcosine dehydrogenase and dimethylglycine dehydrogenase.

Anti-M8 AMAs and Anti-M9 AMAs in PBC

Two other sets of AMAs have been claimed to be specific to PBC and, like anti-M4, important in prognosis of disease progression. One of these recognizes a mitochondrial target categorized as M8. This is an outer membrane, nonorgan-specific, trypsin-sensitive antigen, detectable by CFTs and ELISAs but not by IB. To date, M8 is defined only by the protocol for its preparation. The other specificity, categorized as M9, was defined in terms of a trypsin-insensitive constituent of the inner membrane of liver mitochondria. However, it has since been identified as the nonmitochondrial, cytoplasmic enzyme, glycogen phosphorylase, which presumably co-purifies with inner-membrane fragments on ultra-centrifugation. Hence, anti-M9 antibodies can no longer be considered as AMAs.

Other AMAs

Naturally Occurring Anti-Mitochondrial Antibodies

Sensitive detection methods reveal that sera of healthy individuals exhibit a spectrum of naturally occurring anti-mitochondrial antibodies (NOMAs), perhaps reflecting an arm of the normal immunoregulatory network, and/or a history of exposure to microbial antigens with structures that mimic those of mitochondrial constituents. Where NOMA reactivities against particular antigens have been studied, their fine specificities have been shown to differ from those of disease-associated AMAs recognizing the same molecular species. Interestingly, it has been reported that there is a relative lack of NOMA in patients with PBC, which might be a clue to their normal role in immune regulation.

AMAs Arising from Tissue Damage

Following acute myocardial infarction, many patients demonstrate the short-term production of AMAs against human heart mitochondria. These cross-react against mitochondria from human skeletal muscle, but not with heart mitochondria of other species. Similarly, synovial B-cells in rheumatoid arthritis have been reported as producing AMAs, the finding being interpreted as reflecting local tissue destruction. Such an interpretation may also apply to the demonstration, in insulin-dependent diabetes, of AMAs against the mitochondrial enzyme of pancreatic β -islet cells, glycerophosphate dehydrogenase.

Pathogenetic AMAs against the Adenine Nucleotide Transporter

Myocarditis and dilated myocarditis are diseases related to viral infection, and (independently of the anti-M7 AMAs described above) are characterized by the production of organ-specific

AMAs directed at the mitochondrial adenosine diphosphate/adenosine triphosphate (ADP/ATP) carrier. These antibodies are cytotoxic when tested against guinea pig ventricular myocytes, and in mouse heart, where the transport activity of the carrier has been shown to decline in a manner related to the decrease of cardiac function. The production of these AMAs declines over a period of 2–3 months, and it has been speculated that the underlying mechanism might involve molecular mimicry with a viral constituent. However, they may arise as a secondary response to virally induced tissue injury.

Glossary

Ca²⁺ micropools Areas in the cytoplasm created by the opening of channels in the endoplasmic reticulum, in which the concentration of Ca²⁺ may transiently exceed 20 μ M. The channel in the endoplasmic reticulum is gated by 1,4,5-inositol-*tris*-phosphate (InsP3), produced as a consequence of the interaction of specific agonists with receptors in the plasma membrane.

Ca²⁺/O ratio The stoichiometry between Ca²⁺ accumulated and oxygen consumed during the uptake of Ca²⁺, driven by the activity of the respiratory chain.

Ca-phosphate deposits in the mitochondrial

matrix Precipitates in the matrix of mitochondria that have accumulated Ca²⁺ and phosphate. Composed mostly of amorphous hydroxyapatite and also organic components, for example, adenosine triphosphate (ATP) and adenosine diphosphate (ADP).

Chemical theory of mitochondrial energy conservation

A theory claiming that energy from the activity of the respiratory chain is conserved in the form of a hypothetical

high-energy intermediate formed on one of the components of the respiratory chain.

Chemiosmotic theory of energy conservation A theory claiming that energy in mitochondria is conserved in the form of a separation of charges across the inner membrane.

Electrophoretic uniporter A still unidentified proteinaceous system that mediates the charge-uncompensated transfer of Ca²⁺ across the inner mitochondrial membrane. Now characterized as a Ca²⁺-selective channel.

Limited accumulation of Ca²⁺ Accumulation of limited amounts of Ca²⁺ in the absence of simultaneous accumulation of inorganic phosphate.

Massive accumulation of Ca²⁺ Accumulation of large amounts of Ca²⁺ and inorganic phosphate as insoluble deposits in the mitochondrial matrix.

Na⁺/Ca²⁺ exchanger A system that promotes the release of mitochondrial Ca²⁺ in exchange for cytosolic Na⁺. Now identified with NCLX, a member of the Na⁺/Ca²⁺ exchanger protein superfamily.

The story of mitochondrial Ca²⁺ transport, now about 50 years old, has had ups and downs: the most important properties of the process were established in a feverish period of activity that followed its discovery. The uptake process was recognized to be mediated by an electrophoretic uniporter, and to be coupled to a release route that exchanges Na⁺ for Ca²⁺ with a probable 3:1 stoichiometry (a H⁺/Ca²⁺ exchanger was also found to release Ca²⁺ in some mitochondrial types). It was soon recognized that the Ca²⁺ cycle regulates two tricarboxylic (TCA) cycle dehydrogenases and pyruvate dehydrogenase-phosphate phosphatase in the mitochondrial matrix, thus controlling the delivery of reducing equivalents to the respiratory chain and, ultimately, the synthesis of adenosine triphosphate (ATP). The uptake of Ca²⁺ may also be accompanied by that of inorganic phosphate, resulting in the precipitation of insoluble Ca²⁺-phosphate deposits (amorphous hydroxyapatite) in the matrix. The precipitation of Ca²⁺ and phosphate was proposed to be a mechanism to enable cells to survive (brief) periods of cytosolic Ca²⁺ overload. It was also suggested to have a potential role in the physiological calcification process. Disappointingly, the affinity of the uptake system for Ca²⁺ was soon found to be at least one order of magnitude lower than what would have been necessary to efficiently handle Ca²⁺ in the concentration range of the bulk cytosol. This dampened the initial excitement very significantly, and initiated a protracted period of lower interest in the process. The key problem was that of reconciling the poor affinity of the uptake system, which would negate its involvement in the regulation of cell Ca²⁺, with evidence showing that the system was nevertheless active *in situ*. The paradox was eventually

solved by the demonstration that the concentration of Ca²⁺ in the bulk cytosol did not reflect the concentration in the vicinity of mitochondria, where it could transiently reach values even higher than 20 μ M, thanks to the agonist-mediated release of large amounts of Ca²⁺ from vicinal endoplasmic reticulum. The finding thus showed that mitochondria could, indeed, efficiently regulate cytosolic Ca²⁺ in spite of their low affinity for it. It initiated a robust revival of the process, which has now become again a hot topic. As a result of the renewed activity in the area, results have also appeared on the (molecular) characterization of the components of the transport process: the electrophoretic uniporter, which has now been characterized as a Ca²⁺-selective channel, and the Na⁺/Ca²⁺ exchanger, which has been identified as NCLX, a member of the Na⁺/Ca²⁺ exchanger protein superfamily.

The interplay of mitochondria with Ca²⁺ is of central importance to cell biology. Following its discovery 50 years ago, the standing of the process in the panorama of cell science has had an oscillatory pattern: immediately after its discovery, it enjoyed a period of great interest and popularity. For reasons that will be discussed, popularity and interest did not last long, and were followed by a protracted phase of essential neglect. Then, in the 1990s, the process suddenly initiated a vigorous revival that is still in full swing today. This article will offer a detailed coverage of the origins and coming of age of the topic, which, as is evident from the literature, are poorly known. It will only briefly discuss the more recent developments, as they have been handled in a number of comprehensive reviews. Historically, the critical year was 1961, when it was discovered that isolated mitochondria took up large amounts

of Ca^{2+} from the medium in a reaction that depended on respiratory energy. This landmark finding was the first direct demonstration of the ability of mitochondria to transfer Ca^{2+} to their internal space; however, numerous indirect hints had appeared in the preceding decade, suggesting that the exposure of mitochondria to Ca^{2+} resulted in its penetration into the organelle. Most of this indirect evidence came from experiments on mitochondrial swelling, which was a very popular experimental topic in the 1950s. For instance, it had been found that Ca^{2+} caused a large-amplitude swelling of isolated mitochondria, a finding that was not related – it must be remembered that those were the prechemiosmotic days – to osmotic causes, but to the stimulation of the synthesis of an endogenous uncoupling agent, or to the activation of hypothetical mitochondrial contractile elements. More direct evidence for the penetration of Ca^{2+} into mitochondria was actually provided by a 1953 study that had found that most of the Ca^{2+} of heart homogenates was recovered in the mitochondrial fraction. The study had directly corroborated the observation with the finding that mitochondria incubated with Ca^{2+} , indeed accumulated it (Table 1). Unfortunately, however, the authors (EC Slater and KW Cleland) had discounted the result as an artifact, because the work had been performed at 0° , that is, under conditions that the authors presumed would not support metabolic activities by mitochondria. Two years later, another study had come closer to demonstrating that respiring mitochondria could indeed take up Ca^{2+} . The study had found that Ca^{2+} , well known at that time as an uncoupler of oxidative phosphorylation, behaved peculiarly, that is, it activated the resting respiration of isolated mitochondria reversibly, instead of irreversibly as orthodox uncouplers do (Figure 1). Thus,

Ca^{2+} behaved like adenosine diphosphate (ADP), and the study even determined that the amount of Ca^{2+} necessary to elicit the same amount of extra oxygen consumption by mitochondria was two-third times that of ADP. The concept of a Ca:O stoichiometry (later due to become an important parameter of the coupling efficiency of mitochondria) was, thus, established *ante litteram*. Clearly, the author of the article, B Chance, had found that Ca^{2+} had somehow become expended as it activated respiration, which was another way of saying that it had become bound to mitochondria. Remarkably, this study had appeared 6 years before the evidence for Ca^{2+} uptake by mitochondria would become direct and unambiguous. Something else, which is worth mentioning, had also happened before the historical 1961 date. NE Saris, a postdoctoral fellow in the laboratory of Chance in the summer of

Table 1 Ca^{2+} uptake by heart mitochondria

<i>Ca²⁺ content of mitochondria (μmoles per mg protein)</i>		
<i>Uptake medium</i>	<i>EDTA-washed preparation (%Δ)</i>	<i>Saline preparation (%)</i>
no Ca^{2+}	0.0015	0.083
0.1 mM Ca^{2+}	0.068+~450	0.127~50

Heart mitochondria were prepared either in saline, or in saline plus 10-mM EDTA. The reaction medium contained 0.135-M KCl, 20-mM phosphate, 0.6-mM Ca^{2+} . Incubation was at 0° . After 30 min mitochondria were sedimented by centrifugation, and Ca^{2+} was determined in the supernatant. Adapted from Slater EC and Cleland KW (1953) The effect of calcium on the respiration and phosphorylative activities of heart muscle sarcosomes. *Biochemical Journal* 55: 566–580.

Figure 1 Simultaneous recordings of respiration (black trace) and NADH (diphosphopyridine nucleotide, called DPNH in the 1950s) oxidation (gray trace) in isolated guinea pig liver mitochondria. Oxygen (O_2) consumption was recorded as an upward of the platinum microelectrode trace: the medium (K^+ -free, isotonic, temperature not specified) contained a respiratory substrate (glutamate), but the respiration was maintained at a low level (state 4 rate) owing to the absence of the phosphate acceptor ADP. The legend does not state it explicitly but 4.5-mM phosphate was also present, judging from the legends to other figures in the article. Addition of ADP caused a burst of O_2 consumption (state 3 rate) that ceased when all ADP had been transformed into ATP. The addition of a pulse of Ca^{2+} induced a similar reversible increase of the respiratory rate. A second addition of Ca^{2+} -activated respiration indefinitely. NADH (DPNH) oxidation (not discussed in the text) was recorded as an upward deflection of the spectrophotometric trace, which reflects the decrease of optical density of the mitochondrial suspension at 340 mμ. The oxidation of NADH (DPNH), which accepted the reducing hydrogen from the substrate at the proximal end of the respiratory chain, was an alternative way of expressing the changes in respiratory rate induced by ADP and by Ca^{2+} . Reproduced from Chance B (1956) On possible mechanism for the control of electron transport in the respiratory chain. In: Liebecq C (ed.) *Proceedings of the 3rd International Congress of Biochemistry, Brussels 1955*, pp. 300–304. New York, NY: Academic Press.

Figure 2 pH changes induced by the addition of Ca^{2+} to a mitochondrial suspension. Rat liver mitochondria were prepared by a conventional cell fractionation procedure. The medium contained 50-mM sucrose, 40-mM KCl, 4.5-mM succinate, 1.9 mg of mitochondrial protein per ml. The starting pH was 7.4, and the temperature 20.23 °C. The additions of Ca^{2+} were made at the points of deflection of the trace. The final concentration of Ca^{2+} added was 91 mM. Adapted from Saris NE (1963) The calcium pump of mitochondria *Societas Scientiarum Fennica. Commentationes Physico-Mathematicae* 28: 3–59.

1959, had discovered that the addition of Ca^{2+} to liver mitochondria induced a pH drop in the medium. He had explained the observation on the basis of the formation of a $\text{H}^+/\text{Ca}^{2+}$ gradient resulting from the transport of the latter ion into mitochondria. Those were important observations and explanations (Figure 2), because they were compatible with the mechanism for the uptake of Ca^{2+} that would become recognized much later with the triumph of the chemiosmotic concept. Saris published his first observations in 1959 in an obscure Finnish journal (where they went predictably unnoticed), and continued his experiments demonstrating that the Ca^{2+} -induced pH cycle was actually linked to the uptake of Ca^{2+} by isolated mitochondria. He summarized the results in his PhD Thesis, which, however, only appeared in 1963.

Discovery of the Ca^{2+} -Uptake Process

Nothing significant then happened in this area until 1961, when two groups, working at Johns Hopkins and at the University of Wisconsin, at last succeeded in unambiguously demonstrating that isolated kidney mitochondria took up large amounts of Ca^{2+} in a process that depended on the activity of the respiratory chain (Figure 3); the uptake was inhibited by uncouplers of oxidative phosphorylation, showing that the respiration had to be coupled. Actually, only the study of the Johns Hopkins group showed the orthodox response of the process to all inhibitors, fully justifying the conclusion that the uptake of Ca^{2+} was a means to harvest the energy made available by the respiratory chain. The study of the University of Wisconsin group had some inconsistencies, for example, it found that the uptake process was inhibited by some uncouplers but not by all, and by antimycin A but not by cyanide. The conclusion of the Wisconsin group was, thus, that “the process of Ca^{2+} uptake was not directly dependent on

Figure 3 Uptake of Ca^{2+} by isolated rat kidney mitochondria. Mitochondria were isolated by a conventional cell fractionation procedure. The reaction medium (isotonic NaCl, pH 7.0 at 30 °C), contained a respiratory substrate (succinate), ATP, Mg^{2+} , and 2.5-mM radioactive Ca^{2+} . At the end of the incubation, mitochondria were sedimented by centrifugation, and radioactivity was measured in the supernatant in a Geiger counter. Reproduced from Vasington FD and Murphy JV (1962) Active binding of Ca^{2+} by mitochondria. *Journal of Biological Chemistry* 237: 2670–2677.

oxidative phosphorylation, nor on the activity of the entire respiratory chain, but only on the function of its mid-portion.” Remarkably, however, both studies had found that the uptake of Ca^{2+} , even if energized by the respiratory chain, also required the presence of ATP (Figure 4). As the uptake was not inhibited by oligomycin, ATP was evidently not used as a source of energy. The reason for the necessity of ATP was only rationalized a couple of years later, when it was shown by E. Carafoli that ATP was taken up by mitochondria alongside with Ca^{2+} . ATP, however, could also be used as a direct energy source for the uptake process, as it was soon found that it could support the uptake of Ca^{2+} in the absence of respiratory chain activity (i.e., in the presence of respiratory inhibitors), in which case the process was inhibited by oligomycin.

The two first studies, and other that followed immediately afterwards, had established that the amounts of Ca^{2+} that could be accumulated were hundreds of times greater than the original mitochondrial content. However, these large amounts could only be accumulated in the presence of inorganic phosphate. In its absence, the accumulated amounts were much smaller: two uptake conditions were, thus, soon defined, the limited and the massive uptake. The requirement for phosphate was understood when it was shown that phosphate accompanied Ca^{2+} on its way to the mitochondrial matrix, to precipitate it there as an insoluble salt. Soon, the Ca-phosphate deposits were visualized in the electron microscope within the mitochondrial profiles as electron dense granules (Figure 5). They were even isolated and shown to be mostly composed of hydroxyapatite, the principal mineral

Figure 4 Dependence on ATP for Ca^{2+} uptake by kidney mitochondria. Mitochondria were isolated from the kidney of a vitamin D-deficient rat by a conventional cell fractionation procedure and incubated for 5 min at 30 °C in a medium (isotonic sucrose-KCl) containing a respiratory substrate, Mg^{2+} , various amounts of ATP, and about 300-mM radioactive Ca^{2+} . At the end of the incubation, mitochondria were sedimented by centrifugation, and radioactivity measured in the supernatant in a Geiger counter. Reproduced from De Luca HF and Engstrom GW (1961) Calcium uptake by rat kidney mitochondria. *Proceedings of the National Academy of Sciences of the United States of America* 47: 1744–1750.

Figure 5 Electron-dense calcium-phosphate precipitates in isolated rat liver mitochondria after accumulation of Ca^{2+} and phosphate. Mitochondria were isolated by a conventional cell fractionation procedure. The composition of the medium for the uptake reaction is not specified in the legend but, according to the reference quoted, it contained isotonic NaCl at pH 7.0, a respiratory substrate (succinate), 4.0-mM phosphate, 3.0-mM ATP, and 4.0-mM Ca^{2+} . The incubation lasted 20 min at 30°. Mitochondria were then sedimented by centrifugation, fixed in OsO_4 , and observed in an electron microscope, $\times 8,000$. Reproduced from Greenawalt JW, Rossi CS, and Lehninger AL (1964) Effect of active accumulation of calcium and phosphate ions on the structure of rat liver mitochondria. *Journal of Cell Biology* 23: 21–38.

component of bones. They also contained organic components, among them ATP and ADP. The presence of ATP and ADP in the granules explained the requirement of ATP for the Ca^{2+} -uptake process even when it was energized by the respiratory chain, no granule formation occurred, and no granules

could be isolated, in the absence of ATP. As mentioned, ATP (or ADP) was accumulated together with Ca^{2+} and phosphate; the uptake of adenine nucleotides only occurred when phosphate was also taken up, and when the amounts of Ca^{2+} and phosphate accumulated were massive. In all probability, adenine nucleotides stabilized the Ca-phosphate deposits, or perhaps primed their precipitation. The uptake of ATP was inhibited by the classical blocker of the ATP/ADP carrier, but the inhibition was only partial when the amounts of accumulated Ca^{2+} and phosphate were massive, a finding that was attributed to the damage to the mitochondrial membrane by the excess accumulation of Ca^{2+} and phosphate. The precipitation of the insoluble deposits initiated on the cristae, and then, as the precipitates grew in size, the deposits moved to freer spaces in the matrix. The simultaneous accumulation of phosphate was exploited as a convenient laboratory device to increase the amount of Ca^{2+} than could be stored inside mitochondria, and also gradually became recognized as potentially important in physiology. Early after the discovery of the Ca^{2+} - and phosphate-uptake process, interest developed in the possibility that the storage of insoluble Ca-phosphate salts within mitochondria could have a role in the process of physiological calcification. As the biological potential to undergo calcification is ubiquitously present in animal tissues, it was appealing to relate the transport of Ca^{2+} by mitochondria, and, in particular, the deposition of Ca^{2+} -phosphate granules, to the process. A.L. Lehninger, thus, proposed that mitochondria could concentrate Ca^{2+} and phosphate to a level that could not be attained spontaneously in the extracellular fluids. Micropackets of colloidal dimensions would then dissociate from the large Ca^{2+} -phosphate granules and would somehow pass through the mitochondrial membranes to be exported from the cell and to the calcification sites; the finding that the hydroxyapatite formed inside mitochondria remains indefinitely amorphous would facilitate the process. Clearly, the transfer of the Ca^{2+} deposits through the mitochondrial membrane and their diffusion to the calcification sites is a major problem. Some indirect evidence in favor of the proposal has appeared over the years, but convincing experimental validation has yet to appear.

The storage of massive amounts of Ca^{2+} and phosphate inside mitochondria was also proposed to be a means to clear excess Ca^{2+} from the cytosol whenever pathological events would permit its abnormal entry from the extracellular spaces. Mitochondria, thus, have come to be regarded as devices that would permit cells to survive a transient period of cytosolic Ca^{2+} overload. The concept was reinforced by the finding that the hydroxyapatite deposits in the matrix remained indefinitely amorphous, that is, in a state that would facilitate their dissolution, and the gradual release of Ca^{2+} from mitochondria (once the Ca^{2+} emergency had passed) at a rate compatible with the exporting capacity of the plasma-membrane systems.

Early Findings on the Mechanism of the Uptake Process

In the wake of the early findings, mitochondrial Ca^{2+} transport rapidly became very popular, and became recognized as an alternative to ADP phosphorylation in the harvesting of the energy made available by the respiratory chain. For a long time,

the findings on the process were interpreted within the framework of the chemical theory of energy transduction; in hindsight, it may seem surprising that the process was not immediately related to the then emerging chemiosmotic theory of energy transduction, for which it evidently provided essential support. Chemiosmosis, however, only crept into the field laboriously, and did not take it over until well into the 1960s. Meanwhile, numerous studies had established the essential phenomenology of the process; thus, the stoichiometry of Ca^{2+} uptake to oxygen consumption was measured, finding that two Ca^{2+} ions were required to elicit the same extra consumption of oxygen elicited by one molecule of ADP, a finding that clearly confirmed the earlier conclusion by B Chance that the Ca^{2+}/O stoichiometry in the transition from resting (state 4) to activated (state 3) respiration was 2–3 times the ADP/O stoichiometry. It also became clear that in the absence of phosphate the small amounts of Ca^{2+} that were taken up were maintained within mitochondria in a dynamic steady state, in which the leak of Ca^{2+} was balanced by its reuptake during the phase of resting respiration that followed the activated phase during which the pulse of Ca^{2+} had been taken up. It was an important finding, as it established the concept of a continuous cycling of Ca^{2+} across the mitochondrial membrane (the mitochondrial Ca^{2+} cycle), its long-term storage in the matrix only occurring when phosphate was also present and taken up. The finding that mitochondria could dynamically take up and release Ca^{2+} had obvious interest in the light of the emerging importance of Ca^{2+} in the regulation of cell activities, and placed mitochondria in a central position as potential regulators of cell function. At that time, however, an element in the scenario was still missing: while the fourth portion of the cycling process was defined, the back portion, that is, the route (mechanism) for the release of Ca^{2+} was not, and was only discovered some years later.

The limited uptake of Ca^{2+} in the absence of phosphate was eventually used to test the proposal of an electrophoretic mechanism for the uptake of Ca^{2+} , which would have been consistent with the increasingly popular chemiosmotic principles. Diffusion potentials were artificially imposed across the mitochondrial membrane, showing that Ca^{2+} indeed traversed the membrane in response to an electrochemical gradient. Uncertainties of the various types complicated experiments aimed at establishing whether the mechanism of the uptake process was purely electrophoretic or partially charge compensated, but the presence of an electrophoretic component in the uptake process became generally accepted. As a result, the process of Ca^{2+} transport, which had been initially described as an active uptake followed by a passive release, became an energetically downhill uptake process, followed by an energetically uphill release leg. The uptake leg of the process was postulated to occur on an electrophoretic uniporter, its study being aided greatly by the discovery of specific inhibitors, the most popular being the histochemical stain Ruthenium Red (about 20 years later a derivative, RU360, was introduced, which specifically inhibited the uptake of Ca^{2+} with an IC_{50} of 0.2–2.0 nM).

The Release Leg of the Mitochondrial Ca^{2+} -Transport Cycle

The release leg of the Ca^{2+} -transport process was eventually identified in 1974, when E Carafoli and co-workers found that Na^+ could specifically release Ca^{2+} from mitochondria (Figure 6). The process was later characterized by the group as a carrier-mediated antiport that exchanged Na^+ for Ca^{2+} . The curve relating the rate of Na^+ -induced Ca^{2+} release to the concentration of extramitochondrial Na^+ had a pronounced

Figure 6 Na^+ -induced Ca^{2+} release from rat heart mitochondria. Mitochondria were isolated by a conventional cell-fractionation procedure. The release of Ca^{2+} was followed isotopically by rapid Millipore filtration after mitochondria had been loaded with Ca^{2+} , labeled with $^{45}\text{Ca}^{2+}$. The medium (pH 7.4, 25°) contained 210-mM mannitol, 70-mM sucrose, and a respiratory substrate (succinate). No substrate was present in (a), in which mitochondria had also been preincubated with rotenone to block the reuptake of the lost Ca^{2+} driven by endogenous respiratory chain activity. In (b), the reuptake of the lost Ca^{2+} had instead been blocked by 10-nM ruthenium red, added 30 s before the addition of Na^+ . The amounts of Ca^{2+} added to the medium were extremely small (between 5 and 10 nmol per mg of mitochondrial protein). In (c), no Ca^{2+} was added, as the rats had been injected intraperitoneally with 180 μCi of $^{45}\text{Ca}^{2+}$ 5 min before being killed. (a) Open circles, 100-mM Na^+ ; triangles, 100-mM K^+ ; closed circles, equal concentration of reaction medium. (b) Open circles, 50-mM Na^+ ; closed circles, equal concentration of reaction medium. (c) Open circles, 5-mM Na^+ , closed triangles, 20-mM Na^+ , open triangles, 50-mM Na^+ ; closed circles, 100-mM reaction medium. Figure 7 Dependence of the initial rate of Ca^{2+} release from mitochondria on the concentration of external Na^+ . Rat heart mitochondria were prepared by a conventional cell fractionation procedure and incubated in a medium containing 120-mM KCl, 10-mM HEPES pH 7.0, 1-mM succinate, 60 nmol of Ca^{2+} , and 2.9 mg of mitochondrial protein in a final volume of 4.0 ml at 25 °C. After 4 min, 0.15 μM ruthenium red was added to prevent the reuptake of the released Ca^{2+} . Then, Na^+ was added to induce the efflux of Ca^{2+} and the rate of Ca^{2+} release, which was constant for at least 1 min, was measured with a Ca^{2+} -specific electrode. Modified from Crompton M, Capano M, and Carafoli E (1976) The sodium-induced efflux of calcium from heart mitochondria. A possible mechanism for the regulation of mitochondrial calcium. *European Journal of Biochemistry* 69: 453–462.

sigmoidal character, with an EC_{50} of about 8 mM (Figure 7); the figure was interesting, as it was within the range of Na^+ concentration in the normal cytoplasm, that is, the rate of Ca^{2+} release from mitochondria changed significantly by relatively small changes of Na^+ in the 4–10-mM range, implying that the efflux of Ca^{2+} from mitochondria could be regulated by physiological changes of the cytosolic Na^+ concentration. The maximal velocity of the Na^+ -mediated release process (about 18 nmol per mg of mitochondrial protein per minute) was about 10 times lower than the V_{max} of the uptake process. The exchanger was found to be particularly active in mitochondria of excitable tissues, for example, heart (a $\text{H}^+/\text{Ca}^{2+}$ -exchange process was later found to preferentially mediate the release of Ca^{2+} from mitochondria that were less Na^+ responsive, e.g., those of liver). The original work on the Na^+ -mediated Ca^{2+} release found that it was inhibited by lanthanides, which also inhibited the Ca^{2+} -uptake process, albeit with a different response to the lanthanide series. Later on, the release process was found to be inhibited much more effectively by benzothiazepines. The most effective was CGP-37157, which has become the inhibitor of choice in the studies of the exchanger.

The $\text{Na}^+/\text{Ca}^{2+}$ exchanger operated in the presence of the large negative membrane potential maintained inside mitochondria by the vectorial operation of the respiratory chain; therefore, it had to operate either electroneutrally or

electrogenically, exchanging more than two Na^+ per one Ca^{2+} . The stoichiometry of the exchange reaction has been debated, but now appears to be settled on three Na^+ per one Ca^{2+} .

The Affinity of Mitochondria for Ca^{2+} Is Too Low for the Regulation of Cell Ca^{2+}

The question of the affinity of the mitochondrial uptake system for Ca^{2+} was obviously important, if mitochondria were to play any role in the regulation of cytosolic Ca^{2+} , they had to be able to interact with it in the concentrations prevailing in the cytosol, that is, in the nM range. At this point, problems soon emerged: numerous measurements with different methods, and on mitochondria from different tissues, invariably yielded K_m values for the uptake process higher than 1 μM , most frequently in the 10- μM range. The problem was further exacerbated by Mg^{2+} , which decreased the Ca^{2+} affinity of the uptake system in the concentrations known to exist in the cytosol. Factors were identified that increased the affinity, for example, spermine, which made mitochondria responsive to physiological concentrations of Ca^{2+} , but the idea gradually gained ground that mitochondria were essentially inactive in the Ca^{2+} concentrations of the cytosol. The rationale for the existence of the sophisticated Ca^{2+} uptake and release system, thus, shifted from the regulation of Ca^{2+} in the cytosol to the regulation of Ca^{2+} within mitochondria themselves, which was an important task, because RM Denton, JG McCormack and co-workers had discovered that two TCA cycle dehydrogenases (α -ketoglutaric dehydrogenase and NAD^+ -isocitric dehydrogenase) and the phosphatase that dephosphorylates pyruvic dehydrogenase were allosterically regulated by Ca^{2+} in the μM range, the production of reducing equivalents to be delivered to the respiratory chain and, ultimately, the synthesis of ATP, thus depended on the precise regulation of Ca^{2+} in the mitochondrial matrix. Therefore, in the physiological conditions of most cytosols, the mitochondrial Ca^{2+} -transporting system would only operate at a minor fraction of its maximal potential, which, however, would still be adequate to translate Ca^{2+} signals inside mitochondria for the purpose of modulating the production of energy.

Considering that in the 1960s and 1970s, it was generally assumed that the concentration of Ca^{2+} in the cytosol oscillated uniformly in the 100–200-nM range, the skepticism on the role of mitochondria in the regulation of cytosolic Ca^{2+} seemed justified, not entirely; however, as a number of findings had shown that mitochondria, regardless of their documented poor affinity for Ca^{2+} , were somehow still able to efficiently take it up Ca^{2+} *in situ*. The original 1953 work by Slater and Cleland had already shown that mitochondria sequestered most of the Ca^{2+} of heart homogenates, and similar work had shown that this was true also of Mn^{2+} , a cation that is transported by mitochondria with the same rules as Ca^{2+} . However, more recent work on the distribution of injected radioactive Ca^{2+} in the tissues of rats had shown that the largest fraction of the radioactivity was recovered in the mitochondrial fraction. Importantly, the fraction of radioactivity recovered in mitochondria decreased very significantly if rats had been previously injected with an uncoupler; evidently, efficient energy-linked uptake of Ca^{2+} by mitochondria had

managed to occur *in situ*, somehow overcoming the poor affinity of the system.

However, the mediocre Ca^{2+} affinity of the uptake system was difficult to circumvent. Actually, the finding that the amount of Ca^{2+} which could be presumably mobilized from mitochondria *in situ* in response to physiological demands was insignificantly low (1–2 nm per mg of mitochondrial protein) added significantly to the general aura of skepticism; by the late mid-1970s, mitochondrial Ca^{2+} transport had lost a large portion of the appeal it had once enjoyed.

New Findings Overcome the Problem of the Low Affinity of the Uptake System

Important findings continued to be made during the period of dampened interest on mitochondrial Ca^{2+} transport, for instance, showing that the uniporter had two Ca^{2+} -conductivity states, and identifying a new path for the release of Ca^{2+} from mitochondria, the permeability transition pore (PTP). Findings also occasionally appeared showing that mitochondria efficiently buffered physiological Ca^{2+} loads *in situ*, for example, in neurons. The large and sophisticated body of information that had become available since the 1960s (summarized in the cartoon in Figure 8) was impressive, but the poor Ca^{2+} affinity of the system remained a formidable barrier that confronted all serious attempts to involve mitochondria in the regulation of cell Ca^{2+} . The barrier was finally removed at the beginning of the 1990s, when S Rizzuto and his co-workers showed that the low nanomolar concentrations of Ca^{2+} routinely measured in the bulk cytosol did not

necessarily reflect those in the vicinity of mitochondria. The conclusion was made possible by the targeting of the Ca^{2+} -responsive photoprotein, aequorin, to the matrix of mitochondria, where it directly monitored the changes of the concentration of Ca^{2+} ; the original experiment, for which bovine endothelial cells were used, showed that plasma-membrane agonists that transiently elevated cytosolic Ca^{2+} surprisingly elicited the rapid and transient increase of mitochondrial Ca^{2+} (Figure 9). The experiment took advantage of the ability of the newly discovered second messenger 1,4,5-inositol-*tris*-phosphate (InsP3) to open a specific Ca^{2+} -release channel in the endoplasmic reticulum. It was a direct demonstration that the mitochondrial Ca^{2+} -transport system responded rapidly to the increase in cytosolic Ca^{2+} induced by physiological stimuli, which in this case were plasma-membrane agonists that generated InsP3. Importantly, no mitochondrial Ca^{2+} response was elicited by adding Ca^{2+} to permeabilized cells to artificially modulate its concentration throughout the cytosol; evidently, the opening of the InsP3-gated channels in the endoplasmic reticulum had generated micropools of Ca^{2+} in the vicinity of mitochondria, in which the concentration of the ion was much higher than in the cytosol at large, and evidently adequate to activate the low-affinity uniporter. Later measurement actually showed that the concentration of Ca^{2+} in these hot spots could reach values in excess of 20 μM . The findings were reinforced by the demonstration of the intimate physical interplay between mitochondria and the endoplasmic reticulum in a number of cell types. They were followed by numerous studies correlating the time response of mitochondrial Ca^{2+} with that of ATP production, which depended on the activation of the Ca^{2+} -responsive matrix

Figure 8 The systems for the control of Ca^{2+} homeostasis in mitochondria. The cartoon shows the three matrix enzymes that are controlled by Ca^{2+} : α -ketoglutaric dehydrogenase (α -KGDH), NAD-dependent isocitric dehydrogenase (NAD-IDH), and pyruvate dehydrogenase phosphate phosphatase, that acts on the substrate PDH-P. The (–) and (+) symbols indicate the negative inside membrane potential maintained by the asymmetric orientation of the respiratory chain carriers in the inner membrane. The (?) symbol next to the $\text{H}^+/\text{Ca}^{2+}$ exchanger indicates that the stoichiometry of the system has not yet been conclusively established. The permeability transition pore (PTP) is engaged in a dashed box to signify that, even if it lets Ca^{2+} through, it is not a *bona fide* Ca^{2+} channel. The uniporter is indicated as a Ca^{2+} -selective channel, as shown by recent findings (see text). The cartoon also shows the reversible (low affinity) binding of Ca^{2+} to negatively charged membrane components (phospholipids?)

Figure 9 Changes of cytoplasmic Ca^{2+} (Ca^{2+}_c) and mitochondrial Ca^{2+} (Ca^{2+}_m) in a HeLa cell clone that stably expressed mitochondrial aequorin or cytoplasmic aequorin. The cells were trypsinized, plated on glass cover slips, left in culture for 2 days, and loaded with fura 2 and coelenterazine (to reconstitute aequorin). Full experimental conditions, including observation of cells, are described in Rizzuto R, Simpson AWM, Brini M, and Pozzan T (1992) Rapid changes of mitochondrial Ca^{2+} revealed by specifically targeted recombinant aequorin. *Nature* 358: 325–327. (a) Measurement of Ca^{2+}_i in three representative single cells. (b) Measurement of Ca^{2+}_i in a monolayer of cells. (c) Measurement of Ca^{2+}_i in a monolayer of cells. In the inset, the (Ca^{2+}_m) peaks (1, mobilization; 2, influx), are compared on an expanded timescale. Reproduced from Rizzuto R, Brini M, Murgia M, and Pozzan T (1993) Microdomains with high calcium close to IP_3 sensitive channels that are sensed by neighbouring mitochondria. *Science* 93: 744–747.

dehydrogenases, and of NAD(P)H generation. They thus provided the long-sought explanation for the paradoxical ability of the uniporter to efficiently operate *in situ* regardless of its very poor affinity for Ca^{2+} , and revived interest in mitochondrial Ca^{2+} transport.

The Molecular Nature of the Mitochondrial Ca^{2+} Transporters

Research on the molecular nature of the mitochondrial Ca^{2+} transporters had been going on since the early days. However, in spite of much work, for a long while the results were consistently meager: the uniporter and the two exchangers defeated

all attempts of molecular characterization, remaining elusive entities. The renaissance of the topic in the 1990s brought new impetus to the search, which has recently seen very substantial progress. Patch clamping work on mitochondria of COS-7 cells deprived of the outer membrane permitted D Clapham and co-workers to characterize the uniporter as a novel, highly selective Ca^{2+} channel that was sensitive to ruthenium red and to RU360, and which had the same divalent cation conductance selectivity of the Ca^{2+} uptake reaction in isolated mitochondria. More recently, the same laboratory performed a genome-wide *Drosophila* RNAi screening that led to the identification of a protein (Letm1) with no appreciable homology to bacterial and plant Ca^{2+}/H^{+} and Ca^{2+}/Na^{+} exchangers that mediated Ca^{2+} uptake coupled to H^{+} extrusion in permeabilized S2 cells. The expressed protein was purified from bacteria, and incorporated into liposomes where it supported the rapid accumulation of Ca^{2+} coupled to the efflux of H^{+} . The authors concluded that Letm 1 was the mitochondrial Ca^{2+}/H^{+} exchanger. However, some of the findings were difficult to reconcile with the conclusion, for example, the exchanger in reconstituted liposomes was blocked by RU 360, which completely blocks the uniporter but has no effect on the Ca^{2+}/H^{+} exchange.

The most recent finding on the molecular identity of the mitochondrial Ca^{2+} transporters is the identification by a composite group of researchers working in Israel, continental Europe, and the United States, of the Ca^{2+}/Na^{+} exchanger as a novel member of the family of Na^{+}/Ca^{2+} exchangers protein superfamily, NCLX. NCLX is the single mammalian member of a phylogenetically ancestral branch of the Na^{+}/Ca^{2+} exchanger superfamily. It performs Na^{+} - or Li^{+} -dependent transport of Ca^{2+} , a feature only shared by the mitochondrial exchanger, and is expressed with particular prominence in skeletal muscle, stomach (smooth muscle), and pancreas, three tissues in which the mitochondrial transport of Ca^{2+} plays a critical role. The authors convincingly corroborated this indirect evidence by showing that NCLX was enriched in mitochondria, where it located to the inner membrane criste. Its overexpression in model cell increased the Na^{+} -promoted mitochondrial Ca^{2+} efflux, whereas its silencing reduced it. The exchange activity in silenced mitochondria was recovered by the expression of heterologous NXCL, and, finally, the NCLX-mediated mitochondrial Ca^{2+} transport was inhibited by the classical inhibitor of the mitochondrial Na^{+}/Ca^{2+} exchanger CGP-37157; the long-sought mitochondrial Na^{+}/Ca^{2+} exchanger, thus, appears to have been identified. Still more recently comprehensive efforts based on a number of predictive *in silico* approaches have led to the identification of a uniporter regulatory protein, and of a two-transmembrane domain, 40-kDa channel-forming protein that fulfills the requirements for being the uptake uniporter.

Mitochondrial Ca^{2+} Transport and the Disease Process

The robust renaissance of mitochondrial Ca^{2+} transport parallels the vigorous expansion of the Ca^{2+} -signaling field. However, Ca^{2+} is an ambivalent messenger; it is essential to the correct functioning of cells as soon as its concentration and

movements are under careful control, but easily becomes a conveyor of death if the control somehow fails. Considering the all-encompassing role of Ca^{2+} in the regulation of cell functions, it is hardly surprising that dysfunctions of the ability of mitochondria to control Ca^{2+} should be harmful to cells. Disease conditions have, for instance, been described in which defects in the respiratory chain prevented mitochondria from efficiently taking up Ca^{2+} , thus depressing the activity of the Ca^{2+} -dependent matrix dehydrogenases and the synthesis of ATP. Significantly, the defects were corrected by limiting the release of Ca^{2+} through the $\text{Na}^+/\text{Ca}^{2+}$ exchange route with the inhibitor CGP 37157. The cellular dyshomeostasis of Ca^{2+} appears to be a strong causative element in a number of neurodegenerative diseases, paramount among them Huntington's disease. Neuronal mitochondria in these diseases experience a condition of stress that compromises their ability to correctly handle Ca^{2+} . Evidence is now accumulating that the abnormal opening of the PTP would promote the release of proapoptotic factors, and of Ca^{2+} itself, from mitochondria to the cytoplasm. The $\text{Na}^+/\text{Ca}^{2+}$ exchanger is also becoming particularly popular as a possible actor in the mitochondrial Ca^{2+} dysfunction in the disease process, especially in tissues such as heart and brain, where the $\text{Na}^+/\text{Ca}^{2+}$ exchange plays a particularly important role in the control of cellular Ca^{2+} homeostasis by mitochondria. Recent evidence has involved it in the

molecular pathogenesis of diseases such as heart failure and neurodegenerative conditions such as Parkinson's and Alzheimer's diseases.

Glossary

Conductance G Expressed in siemens ($S = \text{ampere/volt}$ (A/V)), conductance G is the ratio between the electric current and the applied voltage. At 100 mV (10^{-1} V), a G of 10 pS (10^{-11} S) corresponds to a current of 1 pA (10^{-12} A) generated by about six million monovalent ions per second.

Electrochemical proton gradient Generated by the H^+ -pump activity of mitochondrial inner membrane enzyme complexes, it is commonly expressed in millivolts (mV) as proton motive force ($\Delta p = \Delta\mu_{H^+} / F = \Delta\psi - 60\Delta pH$). $\Delta\psi$ defines the difference in charges, and ΔpH that in H^+ concentrations, between the matrix and the aqueous phase external to the inner membrane. A Δp of 180–200 mV (matrix negative) is normally found, with $\Delta\psi$ contributing for 150–180 mV.

Lipid bilayer It allows the recording of electric activities from artificial planar membranes fused with vesicles obtained from native membranes, or reconstituted with purified proteins.

Mitochondria Organelles composed of an outer membrane, an inter-membrane space, and an invaginated inner membrane delimiting a matrix space that houses crucial metabolic routes.

Patch clamp By means of fine electrodes, it records ionic currents directly from the membrane of isolated cells or organelles, as well as from large lipid vesicles reconstituted with channel-containing membrane fractions (proteoliposomes).

Mitochondria are organelles composed of two membranes, in either of which channels have been detected. However, while channels in the outer membrane (OM) have been rationalized by the overall high permeability of the membrane, the presence of channels in the inner membrane (IM) was unexpected in view of the known implication of the IM in the process of oxidative phosphorylation requiring tightly controlled ion fluxes. After the initial phenomenological description, and despite the largely unknown molecular identity, substantial advances in the functional identification of mitochondrial channels have now disclosed the possibility that these channels may take part in crucial mitochondrial functions, and that their dysregulation triggers dramatic cell events.

Channels in Mitochondrial Bioenergetics

The energy-requiring synthesis of ATP is indispensable for the life of the cell, and is catalyzed by the IM-spanning adenosine triphosphate (ATP)-synthase complex. Following the chemiosmotic principles, ATP-synthases utilize the electrochemical proton gradient that is built up by the active proton translocation from the inner compartment (matrix) of mitochondria outwardly, accomplished by IM enzyme complexes during substrate oxidation. As intuitively expected, mitochondria need to avoid dissipation of the proton gradient by uncontrolled fluxes of protons, and ions in general, toward the negatively charged matrix. Accordingly, it has long been established that across the IM there are tightly regulated ion movements that proceed at a much lower rate than ions through channels, and which are catalyzed by proteins such as: the ATP-synthase; the H^+ -carrier that in brown fat dissipates energy as heat; carriers that accumulate anionic substrates in the matrix, or counterbalance the influx of positive charges carried, for

example, by Ca^{2+} and K^+ . A different reasoning applies to the OM, which is devoid of energy-transducing apparatus, and cannot, therefore, develop a proton gradient. This fact excludes conceptual barriers for the OM permeability properties, and indeed the electric features of OM channels, the first to be identified in mitochondria, have led to assume that, rather than classical ion conducting elements, they act as principal pathways regulating the intense exchange of high-molecular-mass molecules between mitochondria and the rest of the cell.

Functional and Molecular Aspects of Mitochondrial Channels

Outer Membrane Channels

The voltage-dependent anion channel (VDAC, or mitochondrial porin) is the most abundant OM protein, and one of the few mitochondrial channels with known molecular identity. Its presence in all eukaryotes examined so far speaks in favor of a key role for this protein. Extensive electrophysiologic studies – carried out by incorporating purified OM fractions in artificial membranes – have revealed that VDACs from different species have amazingly conserved biophysical behaviors. Paradigmatic is the symmetrical closure upon raising the transmembrane electric field, in that the large conductive (maximally open) state adopted by VDAC at low applied voltages (roughly between ± 10 mV) (Table 1) is drastically reduced (albeit not nullified) as voltage is increased on both directions (positive and negative). Attainment of the lower conducting states, nicknamed ‘closed’, parallels the change of the ionic selectivity from slightly anionic to cationic. Such features, in particular the voltage-dependent permeability, and other biochemical and genetically based findings, have thus frequently suggested that the protein acts as a molecular

Table 1 Main mitochondrial conductances

Location	Name	Maximal conductance (pS)	Major putative role(s)
Outer membrane	VDAC	600–750	Transport of metabolites, MOMP/apoptosis, PTP complex
	Tom40	1000	Protein import
	MAC	2500	Apoptosis
Inner membrane	Miscellaneous	~300	Transport of metabolites
	K _{ATP}	~10	Volume regulation, ischemic preconditioning

Summary of the channel activities present in the OM and IM of mitochondria, and of the putative role attributed to them. For details, see text.

sieve, thereby regulating the process of oxidative phosphorylation, if not the entire cell metabolism.

Three distinct VDAC genes (Vdac1-3) have been identified in mammals. Mice deficient for either Vdac1 or Vdac3 are viable, although showing alterations of mitochondrial functionality and morphology. Conversely, deletion of Vdac2 results in embryonic lethality, which is possibly linked to enhanced activities of mitochondria-dependent death pathways. VDACS from different organisms show little conservation of the amino acid sequence, thus suggesting that the almost overlapping electric picture of all VDACS could arise from similar secondary structures. Indeed, prediction algorithms based on sequence analysis and functional properties have proposed a general feature of the pore's wall formed by antiparallel β sheets, with the hydrophilic amino acids expectedly facing the internal aqueous ion-conducting space. The recent availability of high resolution three-dimensional (3D) structures of mammalian VDAC1 has partly confirmed these predictions, showing that the protein is a 19-stranded β barrel, with an α helix located within the aqueous pore. The α helix might serve as a voltage sensor, or as a filter for ion selectivity. Intriguingly, however, the functional properties deduced from the 3D structures did not correlate with the long-standing electrophysiologic picture of VDAC in artificial membranes. In addition, the same recombinant protein utilized for the structural studies showed substantially different electric behaviors.

Within this issue, it is important to mention that the conserved electric pattern of VDAC was never observed *in situ*. Instead of the typical bell-shaped curve, application of a patch clamp electrode to intact mitochondria has shown that the macroscopic current of the entire OM responded asymmetrically to positive and negative voltages, and, likewise, that single-channel behaviors were never reminiscent of reconstituted VDAC properties. Clearly, these data suggest that VDAC in native membranes is under the control of either OM or inter-membrane regulators that are lost during reconstitution of OM fractions in artificial membranes; or that, despite VDAC abundance, channels different from VDAC are the major contributors to the OM electric behavior. As yet, however, the

physiology and molecular structure of most of such channels are unknown, although – consistent with the present notion of OM functionality – they likely transport metabolites rather than only small ions. Finally, the only attempt to analyze mitochondria in its cellular context (at the presynaptic terminals of large neurons) has demonstrated that the OM displays intense electrical activities especially during synapse activation, which, however, do not resemble those reported for VDAC in artificial membranes.

Of relevance, the electrophysiologic analysis of OM- (or IM-) containing proteoliposomes, and of some membrane components in artificial membranes, has eventually proven the long-lasting hypothesis that most (almost 99%) mitochondrial proteins – encoded by the nuclear genome and synthesized in the cytosol – reach their final destination by passing through large permeation pathways spanning the OM and IM. Specifically, it has been found that both the purified multisubunit translocase of the OM (TOM) (which does not include VDAC) and the TOM component putatively involved in translocation, Tom40, form a pore with a large full open state of around 1000 pS, and with a slight preference for cations (Table 1). These features, which are *per se* consistent with a role of the TOM machinery in allowing permeation of unfolded polypeptides, have been further substantiated by the disturbance to ionic currents provoked by cationic peptides mimicking the mitochondrial targeting domain of several proteins. This perturbation likely reflects transient occlusions of the pore during the passage of the peptides.

Inner Membrane Channels

The *in situ* electric recording of the IM of isolated mitochondria demands that the OM be removed first; this allows expansion of the IM invaginations and formation of a vesicle (mitoplast) sufficiently large to be patch clamped. Except for one type of conductance (called mitochondrial mega- (MMC), or multi-conductance channel (MCC)) showing huge and unselective fluxes of ions, this strategy has been instrumental to the

description of two main kinds of channels, distinguishable by several criteria, not the least the ion selectivity.

Cation selective channels

Following the patch clamping of intact mitoplasts, it has been proposed that the IM harbors more than one type of K^+ channels, which have been discriminated upon the mode of their regulation, the single channel conductance, and, when available, the molecular identity. One of these is the K_{ATP} channel, with a conductance of around 10 pS and no clear voltage dependence, which was found to be active only at low concentrations of matrix ATP (Table 1). The similar action of ATP and drug molecules has then allowed to functionally identify the K_{ATP} channel with the K^+ uniport that, together with anion-conducting systems (see below), is known to guarantee mitochondrial osmotic stability. Indeed, enhancement of K^+ influx under the stressed condition of low matrix ATP renders the channel suitable at serving in the K^+ cycle-based volume regulatory mechanism, especially within the proposed control of mitochondrial oxidation rate by matrix volume changes.

It has also been shown in isolated hearts that the same drugs opening (cromakalin and diazoxide), or closing (glibenclamide, 5-hydroxydecanoate), mitochondrial K_{ATP} channels, enhance or abolish, respectively, the beneficial effects that arise by imposing to the myocardium brief ischemic episodes (named 'ischemic preconditioning'). During these episodes, it has been hypothesized that mitochondria produce moderate amounts of reactive oxygen species (ROS) that, by triggering ROS-quenching mechanisms, or by stimulating cell-survival pathways, protect hearts from the ROS-mediated irreversible injury caused by subsequent prolonged ischemic periods. Thus, the cardioprotective role of K_{ATP} could be rationalized in the mitochondrial depolarization provoked by the channel-mediated K^+ entry, which enhances the rate of substrates oxidation, and hence, stimulates the production of ROS.

The second K^+ channel described in the IM has a larger conductance (of around 300 pS), and is activated by matrix Ca^{2+} (mtBK_{Ca}) (Table 1). Because the channel-mediated K^+ influx causes a mitochondrial depolarization, this channel could serve in ischemic preconditioning as hypothesized for K_{ATP} . However, its opening by matrix Ca^{2+} also entails that mtBK_{Ca} could guard mitochondria against dangerous Ca^{2+} overloads, given that the K^+ -induced depolarization reduces the voltage-dependent entry of Ca^{2+} into the mitochondrial matrix. As for its molecular identity, the similar electrophysiological and pharmacologic features have suggested that mtBK_{Ca} coincides with the BK type K_{Ca} channel ($K_{Ca1.1}$) present in the plasma membrane. However, despite the support to this hypothesis by immunological approaches, it is still debatable whether mitochondrial mtBK_{Ca} coincides with that of the plasma membrane, or, conversely, whether the two molecules share only an antigenic similarity.

Intriguingly, the IM of mitochondria could harbor two other channels that have been previously described in the plasma membrane. One of these is the Ca^{2+} -activated K^+ channel $K_{Ca3.1}$, immunologically and electrophysiologically characterized in mitoplasts from human colon cancer cells (mtIK_{Ca}) (Table 1). The presence of $K_{Ca3.1}$ in mitochondria of other cell types, and the physiologic relevance of its IM localisation, remain, however, to be determined. The other

channel, identical to the plasma membrane voltage-dependent Shaker-type K^+ channel, Kv1.3 (Table 1), has been observed in mitoplasts from lymphocytes of wild-type, but not Kv1.3-null, mice. As proposed, mitochondrial Kv1.3 channels could act in mitochondria-mediated apoptotic cell death (see below).

Finally, it is important to mention the Ca^{2+} transport across the IM, in light of the many reactions controlled by the ion, and the dangerous consequences of mitochondrial Ca^{2+} overloads for the life of the cell. The protein responsible for this passage, the so-called Ca^{2+} uniport, has been recently identified following a combination of genetic strategies, patch clamping of mitoplasts, and other electrophysiological approaches. It has a molecular mass of around 40 kDa, and acts as a Ca^{2+} -selective channel of small conductance (MiCa channel/MCU) (Table 1).

Anion selective channels

The first channel identified in the IM of mitochondria has a conductance of around 100 pS (named mitochondrial Centum pico-Siemens, mCS, or mCtS) (Table 1), and is preferentially permeated by anions. Although several molecules could modulate the channel (e.g., nucleotides, Ca^{2+}), its most prominent feature is the voltage dependence, which opens the channel at nonphysiologic (positive) matrix voltages and closes it at the high negative potentials normally sustained by mitochondria.

To search for the role of this channel, much experimentation has followed the concept that the IM transport of small ions may guarantee fundamental aspects of mitochondrial physiology, such as osmotic stability. Detailed insight into such routes has been provided by monitoring the osmotic swelling of isolated mitochondria that, under the used conditions, is the direct consequence of the ability of a specific solute to cross the IM. Several carrier-mediated pathways have been described, two of which are of interest in the context of the ion channels' theme: the above-mentioned K^+ uniport (which is functionally identical to the K_{ATP} channel) and the inner membrane anion channel (IMAC) that allows the permeation of anions different from phosphate, adenine nucleotides, and other metabolites. The initial classification as channel of IMAC derived from its high translocation rate, not because of the, as yet unknown, molecular nature. Accurate electrophysiological reinvestigations of mCS single channels, and of the entire IM, have provided substantial evidence for the functional homology of IMAC and mCS channels; both conduct anions of different valence, are active at alkaline matrix pHs (i.e., alkaline pHs render mCS channels operative also at negative matrix potentials), and are equally blocked by specific drugs. The broad biochemical and pharmacological characterization of K_{ATP} and IMAC has led to propose that both transport systems are implicated in maintaining mitochondrial volume homeostasis. The particular conditions of IMAC activation in intact mitochondria have suggested that the channel mediates efflux of matrix anions as part of the mechanism designed to protect against excessive swelling.

More recently, by relying on pharmacological tests on isolated cardiomyocytes, it has been proposed that the opening of mCS/IMAC may trigger the metabolic oscillations observed in cells deprived of substrates, which, at the mitochondrial level, give rise to periodic, redox-state transitions, and a

Figure 1 Major putative channels in mitochondrial membranes. The cartoon shows the channels that could be responsible for some of the conductances observed in mitochondrial membranes (listed in **Table 1**). Solid arrows specify the experimentally determined direction of the ion flow through a channel. Conversely, dashed arrows indicate that the direction of the flow is still uncertain. A^- designates anions. No ionic species is indicated for VDAC in view of the largely unselective conductance of the channel. In regions in which the outer and the inner membranes are closely juxtaposed, TOM and TIM together may form a permeability pathway that allows translocation of proteins from the cytosol to the mitochondrial matrix.

continuous switching between dissipation and re-establishment of the proton gradient. As this phenomenon – if uncontrolled – is likely to provoke a whole set of excitability disturbances in the heart, including arrhythmias, mCS channels may thus become important targets of pharmacological heart treatments.

Similar to the TOM machinery, the reconstituted translocase of the IM (TIM) forms permeation pathways with the large conductance (of around 1000 pS) expected for protein-transporting pores (**Table 1**). Complemented by immunologic approaches, this study has also suggested the functional (and molecular) identity of the TIM pore with the MMC/MCC originally described by patch clamping mitoplasts.

A cartoon illustrating the major channels of the OM and IM is present in **Figure 1**.

Involvement of Mitochondrial Channels in Cell Death Mechanisms

Increasingly, it has been reported that mitochondria are implicated in the cell fate through the regulation of the apoptotic process. Apoptosis is a naturally occurring cell death program, which is essential for normal embryonic development and

tissue homeostasis in adults. The process is controlled by a variety of factors, including members of the Bcl-2 family (e.g., the pro- and anti-apoptotic Bax/Bak and Bcl-2, respectively) and mitochondrial proteins of the inter-membrane space (e.g., cytochrome *c*) that, upon release into the cytosol, activate downstream death events. By necessity, passage of these high-mass molecules across the OM calls for a further increase of the already large OM permeability, a process now referred to as mitochondrial outer membrane permeabilization (MOMP). MOMP has been associated with an extremely large single channel conductance, named mitochondrial apoptosis-induced channel (MAC) (**Table 1**), which was observed by patch-clamping proteoliposomes containing OM fractions of cells subjected to apoptotic stimuli. MAC currents are dependent on the presence of Bax, and are abrogated by Bcl-2 overexpression. This has allowed hypothesizing that MAC activity could be related to the capacity of pro-death Bcl-2 family members to insert into the OM and to generate huge pores able to translocate apoptosis-triggering proteins. An alternative explanation entails that the translocation of Bax/Bak to mitochondria could enhance VDAC permeability, but the direct involvement of VDAC in MOMP is still strongly debated.

On the other hand, several other observations suggest that the formation of high conductance pathways in the IM could

play a key role in apoptosis, following the dramatic increase of the IM permeability known as mitochondrial permeability transition (MPT). MPT leads to excessive ion intake by, and swelling of, the mitochondrial matrix, which, in turn, disrupts the OM and releases inter-membrane proteins. Such a process, reported in isolated organelles and in cells challenged with apoptotic stimuli, is caused by the opening of a large, unselective IM pathway, the permeability transition pore (PTP) (Table 1), tentatively identified with the MMC/MCC electric activity. From a molecular point of view, the PTP would be formed by a multisubunit complex that includes proteins located in the matrix (cyclophilin D), IM (adenine nucleotide translocator), and OM (VDAC) proteins. Recently, however, this view has been questioned by studies using mitochondria carrying the ablation of each of these proteins, which have suggested their modulatory, rather than obligatory, role in the PTP system.

Glossary

Cytochrome *bc*₁ complex A multi-subunit complex of the respiratory chain that transfers electrons from ubiquinone to cytochrome *c*.

Cytochrome oxidase A multi-subunit green heme protein of the respiratory chain reducing oxygen gas to water.

Endosymbiont Organism living symbiotically inside another organism.

Kinetoplast The single, giant mitochondrion of a trypanosome cell.

Nebenkern Spiral-like single mitochondrion wrapped around the flagellum of certain spermatozoa.

Mitochondria, the eukaryotic organelles of oxidative phosphorylation, contain their own DNA genome. This genome is much smaller than that in the nucleus and encodes only ~1% of the mitochondrial proteins. Yet it is essential for the formation of fully functional mitochondria.

Discovery of Mitochondrial DNA

Some concepts take the scientific world by storm, but others conquer it only after many skirmishes. The discovery of mitochondrial DNA (mtDNA) belongs to this second category. Biochemists, histologists, and electron microscopists had seen DNA in mitochondria for years, but most of them were not ready for the idea that the DNA really belonged there. This may explain why textbook accounts of mtDNA almost never tell how this DNA was discovered.

After the basic building plan of the eukaryotic cell had been revealed in the early 1950s by the electron micrographs of Palade, Sjöstrand, and others, biochemists embraced de Duve's dogma that every macromolecule had one, and only one, intracellular location. In the analysis of cell fractions, cytochrome oxidase was taken as a marker for the mitochondria, nicotianamide adenine dinucleotide phosphate (NADPH)-cytochrome *c* reductase for the endoplasmic reticulum, and DNA for the nucleus. Given this frame of mind, it is easy to understand why the presence of DNA in mitochondrial fractions was generally attributed to contamination by nuclear fragments. Histochemical DNA stains, such as the Feulgen reaction, also stained the kinetoplasts of Trypanosomes and the 'Nebenkern' of insect spermatozoa, but at that time it was not yet recognized that these structures were, in fact, unusual mitochondria. Massive amounts of extranuclear DNA were also detected in the cytoplasm of amphibian oocytes, but it took many years to realize that this DNA was, in fact, mtDNA whose abundance reflected the enormous amount of mitochondria in these large cells. In 1961, at the Fifth Annual Meeting of the American Society of Cell Biology in Chicago, Hans Ris showed electron micrographs of mitochondria with inclusions resembling the DNA-containing nucleoids of bacteria and made the heretical proposal that mitochondria (and also chloroplasts) contain their own DNA. In a paper that appeared in the following

year, Ris and Walter S Plaut further documented and expanded these observations. Soon thereafter, biochemical and morphological evidence from several groups confirmed the presence of DNA in chloroplasts.

The discovery of chloroplast DNA made biochemists take a fresh look at early findings by Margaret Mitchell and Boris Ephrussi that certain mutations affecting mitochondrial function in the mold *Neurospora crassa* and the yeast *Saccharomyces cerevisiae* were not inherited according to Mendel's laws. It seemed tempting to speculate that the unknown 'extrachromosomal factors' implicated in these mutations were, in fact, mtDNA.

By 1962, the ground for the concept of mtDNA was thus well prepared, but the concept itself was not generally accepted. In retrospect, it seems that the scientific community was waiting for convincing studies that documented the existence of mtDNA by several diverse methods.

One of these studies came from the electron microscopists Margit MK Nass and Sylvan Nass, who were then working at the Wenner Gren Institute of the University of Stockholm. They showed that the matrix of osmium-fixed chick embryo mitochondria contained thread-like inclusions whose appearance after different fixation procedures closely paralleled that of the histone-free DNA nucleoid of bacteria: after fixation with osmium tetroxide, the inclusions appeared clumped and as bars with a diameter of ~400 Å; fixation of the tissues with osmium tetroxide followed by treatment with uranyl acetate before dehydration made them appear as 15–30-Å thin fibers. Even more convincing evidence for the presence of DNA in these inclusions was the observation that the inclusions could be removed by treating the lightly fixed embryonic tissue with DNase. Treatment with pepsin, with RNase, or with DNase-free buffer controls was ineffective. The clarity of these electron micrographs and the careful controls that were included had a compelling impact on cell biologists. MMK Nass and S Nass published their work in two back-to-back papers in a 1963 issue of the *Journal of Cell Biology*. At that time, however, cell biology and biochemistry were still rather different disciplines and most biochemists did not peruse journals devoted to cell biology. It therefore took a while before the findings by MMK Nass and S Nass entered the consciousness of the biochemical community.

At about the same time, Ellen Haslbrunner, Hans Tuppy, and Schatz at the Biochemistry Institute of the University of Vienna were trying to find a biochemical basis for the extra-chromosomal mutations that abolished respiratory function in the yeast *S. cerevisiae*. In the early 1960s, many biochemists were still reluctant to consider the 'respiratory granules' of yeast as bona fide mitochondria, which placed the research by Haslbrunner et al. well outside the mainstream of mitochondrial biochemistry in the United States and elsewhere.

To look for DNA in mitochondria, a biochemical approach was chosen. Yeast mitochondria were purified by the best methods available, and their DNA content was measured by the time-honored 'Diesche' color reaction. A few years before, de Duve and co-workers had shown that centrifuging subcellular fractions to equilibrium in a density gradient often gave a clean separation of different organelles. Surprisingly, the usual sucrose gradients did not separate yeast mitochondria from nuclear fragments, but when sucrose was replaced with the X-ray contrasting agent 'Urografin', the mitochondria formed an extremely sharp band, and DNA was present in only two fractions: most was at the bottom of the centrifuge tube, and a very small amount, but discrete peak coincided exactly with that of the mitochondria. The DNA in the bottom fraction was easily digested by DNase and apparently represented nuclear DNA. The DNA in the mitochondrial fraction was not readily digested by DNase unless the organelles were first disrupted with trichloroacetic acid; presumably, it represented DNA enclosed by the mitochondrial membranes. Its concentration was very constant between different experiments – between 1 and 4 $\mu\text{g mg}^{-1}$ mitochondrial protein. Urografin – purified mitochondria from rat liver, rat kidney, and bovine heart – contained almost 10 times less DNA, between 0.2 and 0.6 μg DNA per mg protein. The typical mammalian mitochondrion was calculated to contain 3×10^{-17} g DNA. Assuming that the DNA was double-stranded, it could encode no more than 1.2 MDa of polypeptide chains. This result was considered important, because it firmly excluded the possibility that mtDNA encoded all of the mitochondrial proteins. Today, this early calculation by Haslbrunner et al. could be challenged on several grounds, yet it came remarkably close to reality: the 13 polypeptides encoded by mammalian mtDNA have a total mass of 0.423 MDa, and the remainder of the coding potential is largely accounted for by genes for ribosomal and transfer RNAs, as well as by the fact that mitochondria usually have more than one copy of their DNA genome.

Properties of mtDNA

Soon thereafter, several laboratories showed that mtDNA from several organisms had a different base composition and sometimes also a different buoyant density in cesium chloride gradients than the corresponding nuclear DNA. Particularly, striking was the observation that mtDNA from mammals was a small double-stranded circle. Late in 1964, the existence of DNA in mitochondria was generally accepted, and efforts focused on its function. Its identity with the 'extrachromosomal factors' affecting respiratory function in *S. cerevisiae* was established by the observations that mtDNA was either altered or missing in the corresponding mutants. Several

laboratories then showed that mitochondria from yeast and *N. crassa* synthesized the three large subunits of cytochrome oxidase, the heme-carrying subunit of the cytochrome *bc*₁ complex, and at least one membrane-bound subunit of the adenosine triphosphate synthase complex.

Sequence and Gene Content

In 1981, Fred Sanger and co-workers published the complete sequence of the 16 569 nucleotides of human mtDNA. This seminal paper provided the first complete sequence of a eukaryotic genome and identified the mitochondrial genes. Subsequent work by others then showed that the size of mtDNA can vary dramatically between different species (Table 1). There are also considerable differences in gene content, whereas mtDNA from humans and most mammals encodes 13 proteins and 24 RNAs (Figure 1 and Table 2),

Table 1 Sizes of mtDNAs from different species

Species	Kilo-base pairs
Mammals	16.5
Fungi	
<i>Saccharomyces cerevisiae</i>	78
<i>Schizosaccharomyces pombe</i>	17
<i>Aspergillus nidulans</i>	32
Plants	

Figure 1 Genes on human mtDNA. 12S and 16S, rRNA of small and large ribosomal subunit; ND1–6 and ND4L, subunits of NADH dehydrogenase; CO I–III, subunits 1–3 of cytochrome oxidase; cyt. *b*, cytochrome *b* subunit of cytochrome *bc*₁ complex; ATPase 6 and 8, subunits of ATP synthase complex; amino acids designate the corresponding tRNAs; D-loop, highly variable gene-free region; O(H) and O(L), sites previously proposed by some as strand-specific replication origins. Reproduced from Attardi G (1986) The elucidation of the human mitochondrial genome: A historical perspective. *Bioassays* 5: 34–39.

Table 2 Genes on human mtDNA

Function	Molecule(s)	Number
Protein synthesis	rRNAs	2
	tRNAs	22
Electron transport	Cytochrome oxidase	3
	NADH dehydrogenase	7
	Cytochrome <i>bc</i> ₁ complex	1

Table 3 Unusual codon usage in mtDNAs

Codon	Universal usage	Mitochondrial usage	Species
CUA	Leucine	Threonine	Yeast
UGA	Stop	Tryptophan	Most species, not plants
AUA	Isoleucine	Methionine	Most species, not plants
AG(A,G)	Arginine	Stop	Mammals
		Serine	Insects
		Arginine	Yeast

that from the freshwater protozoan *Reclinomonas americana* carries no fewer than 97 genes. Sequence comparisons between some of the genes and the corresponding polypeptide products also uncovered the astounding fact that the genetic code of mtDNA differs slightly but significantly from that of nuclear DNA (Table 3). For example, the codon UGA defines 'stop' in the nucleus, but 'tryptophan' in mtDNA from mammals, yeast, and many other species. This unexpected finding explained why so many earlier attempts to identify the protein products of mtDNA by coupled transcription/translation in *Escherichia coli* or reticulocyte lysates had failed.

Outlook

There is no end to the fascinating properties of the mitochondrial genome, and many of these properties still beg an explanation. Why is the mitochondrial genome of mammals one of the most compact genomes known, whereas that of plants and yeast spreads its genes luxuriously over 5, 10, or even 100 of times more DNA? Why has the genetic code diverged from the 'standard' one that is used in the nucleus? Why does mtDNA mutate ~10 times faster than the corresponding nuclear DNA? Why some mitochondria have dozens of copies of their genome? Most importantly, why does mtDNA exist at all? Maintaining its few protein-coding genes from one generation to the next keeps hundreds of nuclear genes

occupied, which seems highly uneconomical. Evolution provides the answer: it is now generally accepted that today's mitochondria are descendants of free-living prokaryotes that entered into symbiosis with other cells and transferred most of their genome to the nucleus of their host. The mtDNA is the small remnant of the genome of these endosymbionts.

As a typical somatic cell has only two copies of a nuclear gene, but as many as a thousand copies of each mitochondrial gene, mtDNA has become a favorite tool for genetic fingerprinting and evolutionary studies. Also, it is now well established that mutations in mtDNA can cause a host of devastating maternally inherited diseases, such as blindness, deafness, muscular degeneration, diabetes, and severe neurodegenerative syndromes. A possible involvement of mtDNA in aging and cancer is under intense investigation. There is also mounting evidence that mutations of mtDNA may impair mammalian fertility and the success of *in vitro* fertilization experiments. Indeed, many of the most exciting functions of mtDNA may yet await discovery.

Mitochondrial Dynamics

L Scorrano, University of Geneva, Geneva, Switzerland

Published by Elsevier Inc.

Glossary

Cristae The folds of the inner mitochondrial membrane; these pleiotropic structures are the site of oxidative phosphorylation.

Dynamins Large ubiquitous guanosine triphosphate (GTP)-hydrolyzing enzymes that participate in fusion, fission, and tubulation of biological membranes.

Microdomain A locale of high concentration of an ion or a second messenger, often limited in space and time.

Tethering The close apposition between the outer mitochondrial membrane and the endoplasmic reticulum.

Introduction

Mitochondria were once regarded as the organelles merely devoted to energy conversion until it was discovered that they regulate apoptosis by releasing cytochrome *c*, the only soluble components of the respiratory chain, as well as other proteins that activate the machinery of cell self-destruction. However, the role of these organelles is not limited to the cell life and death decision, but they are also key decision makers in a variety of cellular cascades that range from Ca^{2+} signaling to cellular movement, to establishment of synapse, even to epigenetics. This functional versatility goes hand in hand with the morphological complexity of this organelle. Mitochondria possess two membranes and their inner membrane can be functionally further subdivided in a boundary membrane and in the cristae membrane, pleiomorphic infolded structures of the inner membrane. Furthermore, in the cytoplasm the organelle can live a solitary life, or be interconnected with other mitochondria to form a network. Shape and morphology are continuously regulated by the balance between fusion and fission events. In the last few years, we learned that mitochondrial fusion and fission are essential for embryonic development, participate in apoptosis, maintenance of dendritic spines, migration of white blood cells, Ca^{2+} signaling, determination of life span, and are affected in several human genetic diseases. This article wishes to offer to the reader an account of the surging field of research on how, why, and when mitochondria fuse and divide, and of the functional and pathophysiological consequences of changes in mitochondrial morphology.

Mitochondrial Morphologies

Mitochondria are the metabolic hub of the cell, ensuring the conversion of the dietary intake into adenosine triphosphate (ATP), the usable energy molecule that is required for most of the endergonic processes. This highly efficient process is carried on by the oxidative phosphorylation, where electrons are extracted from reducing equivalents generated and passed in a stepwise process to molecular oxygen. The energy liberated by the reducing steps is coupled to the pumping of protons and therefore to the generation of an electrochemical gradient

across the inner mitochondrial membrane. According to Mitchell's chemiosmotic theory, the free energy accumulated across the inner membrane is used by the ATP synthase to generate ATP from adenosine diphosphate (ADP) and phosphate. This well-organized system takes advantage of the specialized morphology of the organelle. As mentioned above, mitochondria possess an outer membrane that separates them from the cytosol, and an inner one that constitutes the active site of the oxidative phosphorylation, where the four complexes of the respiratory chain as well as the ATPase reside. The two membranes enclose two aqueous spaces, the matrix, where Krebs cycle is located, and the intermembrane space, where many proteins are stored, including the one and only soluble component of the mitochondrial respiratory chain, cytochrome *c*.

Recent advances in the techniques used to visualize the ultrastructure of the mitochondria unveiled that the inner membrane can be further subdivided into two different compartments, the inner boundary membrane and the cristae (Figure 1). These latter, according to the classic model elaborated in the 1950s by G. Palade, were invaginations of the inner membrane widely opened to the intermembrane space. Nowadays, thanks to the pioneering electron tomography (ET) studies of Mannella and Frey, cristae are identified as a separated compartment, resembling pleomorphic bags connected by a bottleneck called 'cristae junction' to the inner boundary membrane. The bag-like appearance of the cristae has a clear functional consequence on the efficiency of the energy conversion system of mitochondria. Integral proteins of the inner membrane are not distributed in a uniform manner between inner boundary and cristae membrane. Accurate immunoelectron microscopy studies revealed that the complexes of the respiratory chain accumulate in the membrane of the cristae, whereas the components of the machinery for mitochondrial protein import are mostly in the inner boundary membrane. This organization takes advantage of the increased surface of the cristae compared to that of the inner boundary membrane, thus maximizing the condenser capacity of the membrane and increasing the efficiency of the oxidative phosphorylation. On the other hand, it requires specialized machineries that regulate the shape of the organelle and ensure the subcompartmentalization of the inner membrane of the organelle.

A further layer of complexity in the regulation of mitochondrial morphology is introduced by the fact that mitochondria

Figure 1 Mitochondrial ultrastructure: from electron microscopy to electron tomography. A conventional electron microscopy and an electron tomogram of mitochondria from mouse liver hepatocytes are shown. In the electron tomography, the outer membrane is in red, the inner boundary membrane in beige, and the cristae in green. The circled area points to the different appearance of the cristae junctions with the inner membrane.

are often organized in the cytoplasm in a network, a reticulum of interconnected organelles continuously shaped by opposing fusion and fission processes. Interestingly, in different cell types morphology of the mitochondria differs: for example, solitary organelles are retrieved in hepatocytes, whereas in many epithelial cells they form an intricate network of interconnected ones. The case of myocytes is even more interesting, with a zonal distinction in mitochondrial morphology: perinuclear mitochondria are mostly globular, while rod-shaped mitochondria are predominantly retrieved in the subsarcolemmal space. Finally, intermyofibrillar mitochondria have exactly the same size of a sarcomere. Thus, different organizations even in the context of the same cell highlight the requirement for a refined machinery that regulates the processes of fusion and fission which are the basis for the observed steady-state morphology of the organelle.

Mitochondrial Fusion and Fission

The final shape of mitochondria results from the equilibrium between two antagonistic processes, fusion, and fission, that constantly take place. When either of them is blocked, the final morphology of the mitochondria is the consequence of the unopposed progression toward the other side of the equilibrium. Members of the machinery regulating mitochondrial fusion have been identified by the analysis of organellar morphology in collections of mutants of *Saccharomyces cerevisiae*. The shape of mitochondria depends on several guanosine triphosphatases (GTPases) with structural homology to dynamins, large ubiquitous guanosine triphosphate (GTP)-hydrolyzing enzymes that participate in fusion, fission, and tubulation of biological membranes. Proteins that regulate mitochondrial shape share with the prototypical dynamins at least the GTPase domain and a C-terminal coiled-coil domain that can function as GTPase effector domain or to mediate protein-protein interaction. On the other hand, the dynamin-related proteins that impinge on mitochondrial fusion are peculiar in that most of them are integral membrane proteins. We now discuss the properties of mitochondria-shaping proteins of mammals.

Mitochondrial Fission

In mammalian cells, mitochondrial fission depends on dynamin related protein 1 (Drp1), a cytoplasmic large GTPase similar to dynamin that mediates the fragmentation of mitochondria, peroxisomes, and endoplasmic reticulum (ER). Drp1 translocates to mitochondria in response to cellular and mitochondrial cues. Following mitochondrial dysfunction, cytoplasmic Ca^{2+} rises, leading to activation of calcineurin and dephosphorylation of the conserved Ser 637 of Drp1. This residue is phosphorylated by protein kinase A, linking mitochondrial morphology to another crucial second messenger, cyclic adenosine monophosphate (cAMP). The phosphorylation status of this site is dominant over that of Ser 616, controlled by cyclin-dependent kinase 1 to drive mitochondrial fission during mitosis. Mitochondrial Drp1 can then be stabilized on the surface of the organelle by SUMOylation, a process known to subtract molecules to degradation by the ubiquitin-proteasome system.

Fis1 is a membrane protein homogeneously distributed in the outer mitochondrial membrane (OMM) via a transmembrane domain located in the C-terminal region, with only a small portion of the molecule protruding into the intermembrane space (IMS). The cytoplasmic region contains six α -helices, four of which $\alpha 2$ – $\alpha 5$ form two tetratricopeptide repeat (TPR)-like domains, predicted to allow protein-protein interactions. Overexpression of Fis1 induces mitochondrial fragmentation, but since it does not possess enzymatic activity, its role is probably restricted to anchoring effector proteins to mitochondria. Accordingly, fragmentation of mitochondria caused by Fis1 overexpression can be blocked by expression of dominant negative mutant of Drp1. Moreover, Drp1 and Fis1 appear to interact, as judged by cross-linking and coimmunoprecipitation. The Drp1-Fis interaction is a transient event and efficient fission requires dissociation of the complex. Accordingly, genetic modifications of TPR-like domain, which stabilize this complex, abolish fragmentation of mitochondria. Binding to Drp1 is executed by $\alpha 2$ – $\alpha 4$ helices of TPR-like domain, while $\alpha 1$ has a negative regulatory function. However, the absolute requirement of Fis1 for binding of Drp1 to mitochondria is somewhat weakened by the observation that downregulation of Fis1 diminishes Drp1 recruitment to mitochondria only partially, and some

novel receptors, called mitochondrial fission factor (Mff) and mitochondrial division (MiD) 49 and 51 have been recently discovered. Mff, previously identified in a *Drosophila* RNA interference (RNAi) screening for mitochondrial morphology alterations, is a C-tail anchored protein of the outer membrane of the organelle, exposed to the cytosol. Ablation of Mff causes mitochondrial elongation and results in the retention of Drp1 in the cytoplasm, whereas its overexpression induces Drp1 recruitment and mitochondrial fission. Indeed, Mff transiently interacts with Drp1 via its cytoplasmic region. The current model indicates that Mff may facilitate membrane fission by promoting the self-assembly and the GTPase activity of Drp1, probably in conjunction with some yet unknown factors. MiD49 and MiD51 are N-terminal anchored MOM proteins, forming foci or ring-like structures on mitochondria and similarly involved in the recruitment of Drp1 onto mitochondria. The relationship between MiDs and Mff remains unclear and is to be investigated.

Mitochondrial Fusion

Fusion of the OUM is governed by two dynamin-related GTPases – mitofusins 1 and 2 (Mfn1 and Mfn2). They display a very high degree of homology and accordingly a similar structure composed of a terminal GTPase domain, two hydrophobic heptads repeats (HRs) and two transmembrane domains that insert them in the OMM. Nevertheless, they are not functionally equal. GTPase activity of Mfn1 is much higher but affinity toward GTP is lower, seemingly playing slightly different roles in mitochondrial fusion. Mfn1 is responsible for mitochondria tethering *in trans*. The role of Mfn2 is somewhat elusive, but it can be retrieved in heterooligomers with Mfn1 and is suggested to participate in later steps of mitochondrial fusion. In addition, levels of Mfn2 correlate with the oxidative metabolism of skeletal muscle and the proliferation ability of vascular smooth muscle cells, by sequestering the proto-oncogene Ras. Mfn2 also controls the shape of ER and tethers it to mitochondria. On the other hand, at least in

fibroblasts, Mfn1, but not Mfn2, is required for fusion triggered by the inner membrane dynamin-related protein Optic atrophy 1 (Opa1), further complicating the picture.

Opa1 is anchored to the IMM by a transmembrane domain located close to the N-terminus, and most of the protein is exposed to the IMS. In humans, there are eight splice variants of Opa1, while in mice only four. All alternatively spliced exons are located in the GTPase domain on N-terminus. Isoforms of Opa1 are then subject to a complex posttranslational cleavage. A model of sequential cleavage has been proposed in which the *m*-AAA protease paraplegin or AFG3L2, or the *i*-AAA protease Yme1L, produces the lower MW forms of Opa1, on which then the rhomboid protease Parl acts to release soluble Opa1 in the IMS space. So far two functions of Opa1 have been defined: as mentioned above, Opa1 drives Mfn1-dependent fusion of mitochondria. Fusion requires the presence of both long and short forms of Opa1, suggesting that different forms of Opa1 may complex to govern mitochondrial fusion. Opa1 is also crucial for maintenance of the structure of IMM. In contrast to the control over mitochondrial fusion, dynamics of IMM seem to depend exclusively on Opa1. Its downregulation causes the appearance of vacuolar cristae and the widening of the cristae junctions, as a consequence of the disruption of a complex comprising at least IMM and IMS forms of the protein. A cartoon depicting our current knowledge of the players involved in mammalian mitochondrial fusion is presented in Figure 2.

Mitochondrial Tethering to the ER

Mitochondria are often found in close association with other cellular structures, ranging from cytoskeletal components to organelles, to the plasma membrane. Probably the best characterized interaction, and the one for which mitochondrial dynamics has been proposed to play a role, is that with the ER, which is not only structural, but also functional, impacting on transport of proteins, Ca^{2+} signaling, and cell death. Since

Figure 2 A cartoon of the key players in mitochondrial fusion and fission and tethering to ER. Mitochondria-shaping proteins and other proteins involved in the fission and fusion machinery are depicted. For a detailed description, the reader is referred to the main text.

the 1970s ultrastructural studies proposed the existence of a close physical relationship between ER and mitochondria in animal and plant cells. This was confirmed more recently by fluorescence microscopy and ET. Up to 20% of the mitochondrial surface is in close apposition with the ER membrane, and the two organelles move in synchrony and exchange several metabolites. This suggests that the machineries of mitochondrial morphology and tethering are somehow connected, as testified by several emerging studies.

A complex formed by some mitochondrial morphology proteins was found to link ER to mitochondria in yeast. The ER-mitochondria encounter structure (ERMES) is formed by Mmm1, localized on the ER membrane, and Mdm10, on the OMM. It comprises also Mdm12 and Mdm34, which are essential for the Mmm1–Mdm10 binding. Mutations associated with one of the ERMES components cause lipid reduction and defects in ER–mitochondria lipid transfer.

Mfn2 is the first mammalian protein identified that directly acts in maintaining ER–mitochondria linkage. It is present in both organelles and regulates their morphology. Mfn2 is enriched in MAMs and connects ER to mitochondria via direct interactions between the protein localized in the ER and Mfn1 or the same Mfn2 present in the OMM. Ablation of Mfn2 causes the destruction of the typical tubular ER structure, forming large vesicles. Moreover, it slows down mitochondrial Ca^{2+} uptake, as a consequence of the increased distance between the two organelles that ultimately disrupts the Ca^{2+} microdomain at the interface between the two.

The Role of Mitochondrial Shape in Cell Function

In the last few years, we learned that changes in mitochondrial shape influence crucial cellular functions, from Ca^{2+} signaling to generation of reactive oxygen species, to neuronal plasticity, to muscle atrophy, to lymphocyte migration, and even to life span. Why is mitochondrial morphology so important for cellular physiology? We think that a few aspects could account for this: compartmentalization achieved by mitochondrial localization, the mitochondrial shape–function relationship, and effects of mitochondrial shape on viability. Mitochondria localize where high ATP amounts are required, or where Ca^{2+} signaling needs to be regulated, as if they are movable tuners of signaling events. Not surprisingly, mitochondrial movement is coordinated with shape changes, in order to produce organelles whose size is compatible with their movement. For example, the expression of pro-fusion shaping proteins decreases mitochondrial movement along axons and dendrites and consequently the amount of dendritic spines and synapses, whose formation or maintenance probably requires locales of high mitochondrial ATP production. Mitochondria-shaping proteins can also influence organellar function. Back in the 1960s, Hackebrock described the classical transition from the orthodox morphology of quiescent ‘state 4’ to the condensed one of respiring, ‘state 3’ mitochondria, showing a clear structure–function relationship for mitochondria. Recently, an association between different phosphorylation abilities, nutrient availability, induction of catabolic processes such as autophagy and mitochondrial morphology has been unveiled; however, an unequivocal relationship between P/O ratios (the number of

ATP molecules produced per oxygen molecule oxidized) and mitochondrial morphology is lacking, raising the question of whether the two are directly linked. Finally, mitochondria-shaping proteins have been reported to play a crucial role in apoptosis, as will be described extensively in the next section.

The Role of Mitochondrial Shape in Cell Death

Several reports indicate that mitochondrial shape and ultrastructure vary during apoptosis. We will review the evidence implicating the mitochondria-shaping proteins in cell death and the proposed mechanisms by which they might influence it.

Mitochondrial Fragmentation

The group of J.C. Martinou originally reported that during neuronal apoptosis mitochondria fragment. Subsequent studies by the group of R. Youle discovered that this apoptotic fission occurs in most cell types and can be blocked by a dominant negative mutant of Drp1, limiting cell death. In the membrane, Drp1 does not distribute homogeneously but forms foci, which usually colocalize later with scission sites. Interestingly, upon apoptotic stimulation at least two other proteins colocalize in foci: Mfn2 and the pro-apoptotic member of the Bcl-2 family Bax, which is required for outer membrane permeabilization. Our understanding of these foci remains elusive, but several lines of evidence suggest that foci may serve as platforms for cross-talk between pro- and anti-apoptotic as well as fusion and fission molecules. Interestingly, Drp1 seems to control the release of cytochrome *c* but not of the other pro-apoptotic factor second mitochondrial activator of apoptosis/direct IAP binding protein with low pI (Smac/DIABLO) from mitochondria, calling for a deeper understanding of the role of Drp1 in outer membrane permeabilization and in the cross-talk with the members of the Bcl-2 family.

Cristae Remodeling

Under basal conditions, the majority of cytochrome *c* is located in the cristae, where the complexes of the respiratory chain reside. To enable its complete release during apoptosis, cytochrome *c* is redistributed to the peripheral IMS in a process discovered by our laboratory and christened ‘cristae remodeling’, characterized by fusion of individual cristae and widening of the narrow cristae junctions.

Remodeling of the cristae occurs in response to a variety of apoptotic stimuli, including pro-apoptotic members of the Bcl-2 family such as Bid, Bim, Bnip3, and Bik. In the latter case, remodeling seems to be mediated by Drp1-dependent mitochondrial fission, thereby linking the outer to the inner side of mitochondrial shape changes during cell death. In accordance with its proposed function in cristae biogenesis, Opa1 is the master regulator of the shape of the cristae and therefore of the rate and extent of cytochrome *c* during apoptosis. This function depends on its GTPase activity, on its oligomerization, and on the efficient production of the soluble forms of the protein controlled by the rhomboid protease Parl. During apoptosis, this Opa1-containing oligomer is targeted and disrupted, allowing the complete release of cytochrome *c* and the progression of the apoptotic cascade.

Conclusions and Perspectives

The field of mitochondrial dynamics is very young and expanding. The recent discoveries that the shape of the organelle is linked to many pathophysiological processes, the availability of molecular tools to investigate if and how shape and function go hand in hand, and the cross-field interest are all good omens for intense research that will further elucidate the structure–function relationship of mitochondria.

Glossary

Self-splicing The intrinsic ability of some introns to remove themselves and link together the two adjacent RNA exons, by transesterification reactions.

Spliceosome The large RNA–protein body upon which splicing of nuclear messenger RNA precursors occurs.

Suppressor gene A gene which, by mutation, is able to eliminate the effects of a mutation in another gene.

Transporter outer membrane–transporter inner membrane (TOM–TIM) proteins Proteins forming receptor complexes that are needed for translocation of proteins across the mitochondrial outer (TOM) or inner (TIM) membrane.

Mitochondria possess their own genome, which encodes a small part of the proteins that make up the organelle. The remaining proteins, that is, the majority, are encoded by the nuclear genome. Mitochondrial life thus depends on the coordinated expression and interaction of nuclear genes and genes present on the organellar genome (mitochondrial DNA (mtDNA)) itself. Although mtDNA encodes very few subunits of the energy-transducing complexes of the inner mitochondrial membrane, these subunits constitute the key elements of the overall process: cytochrome *b* for the reductase activity, cytochrome *c* oxidase subunit 1 for the oxidative activity, and Atp6 for the synthetase activity. The genes coding for these three subunits are always located in the mtDNA in all eukaryotes, whether fungi, protists, animals, or plants. The mtDNA is supposed to be a remnant of a prokaryotic genome that would have originated from a symbiotic event between different cellular species. As the majority of the prokaryotic genes would, however, in the course of evolution, have migrated to the nucleus of the new cell, it is surprising that even today a mitochondrial genome exists. A plausible reason might reside in the compulsory evolution of the formation mechanism of the enzymatic complexes of the inner mitochondrial membrane. This might depend on a topological constraint of the expression and assembly of the different subunits, some of which are very hydrophobic and have to be transcribed, translated, inserted, and assembled from inside the organelle. It follows then that these key genes are present inside the mitochondrion. This would also explain the persistence of mtDNA and its complex machinery of expression for a billion years since the original symbiotic event.

The knowledge of the conjoint expression of both the mitochondrial and nuclear genes involved in energy transduction is best advanced in the study of baker's yeast, essentially due to the extraordinary power of molecular genetics both *in vivo* and *in vitro*.

Yeast as a Model Organism for the Study of Mitochondrial Biogenesis and Function

The facultative anaerobic yeast *Saccharomyces cerevisiae* has provided the main information about mitochondrial biogenesis,

from the discovery of petite mutants by Boris Ephrussi and Piotr Slonimski and their collaborators in the 1950s. This was followed by the exhaustive analysis of mitochondrial genetics in the 1970s in the laboratory of Gif-sur-Yvette and by the identification of mtDNA by Gottfried Schatz, and still remains an excellent experimental organism, owing to its capacity of surviving in the absence of competent mitochondria, to the facility of isolation or construction of mutants (several thousands have already been characterized) and to the possibility of mitochondrial transformation. The search for nuclear genes involved in mitochondrial biogenesis and function is constantly carried out in this organism and the results continually lead to the isolation of functionally homologous human genes. In particular, many mitochondrial disease genes have been identified or studied in this way.

Mitochondrial life depends on the coordinated expression and interaction of nuclear genes and genes present on the organellar genome (mtDNA) itself. The mitochondrial genetic system is required for the synthesis of a limited number of proteins, in particular in yeast of seven highly hydrophobic subunits of the energy-transducing complexes of the inner membrane (Figure 1).

All the processes necessary for the expression of these genes (i.e., transcription, RNA processing and translation), as well as those required for mtDNA maintenance and integrity, take place in the same compartment, the mitochondrion itself, as they occur in a bacterium, the hypothetical mitochondrial ancestor. Also, the different processes are functionally linked, frequently through the activity of proteins exhibiting multiple roles.

Expression of Mitochondrial Genes

Mitochondrial gene expression requires the coordinated interaction of mitochondrial and nuclear-encoded factors: the mitochondrial genome (Figure 1) participates in the process with the genes encoding the 9 S RNA-subunit (*RPM1*) of mitochondrial ribonuclease P (RNase P), the 21S and 15S ribosomal RNAs (rRNAs), a complete set of transfer RNAs (tRNAs), and one protein of the small mitoribosomal subunit, Var1p; in addition, some introns encode proteins necessary for RNA splicing (RNA maturases). The nuclear genome encodes all other factors necessary for mitochondrial genome maintenance and

[†]Deceased.

Figure 1 The mitochondrial genome of *Saccharomyces cerevisiae*. The circular map is in agreement with the genetic results and with the observation that mtDNA replicates by the rolling-circle mode. Different yeast strains contain mtDNA molecules of different lengths (comprised between 70 and 85 bp). These differences are essentially due to the presence/absence of introns and hypothetical open reading frames (ORFs 1–5 in this representation). Yeast mtDNA encodes seven highly hydrophobic subunits of the energy-transducing complexes of the inner membrane, that is, apocytochrome *b* (encoded by the *cyt b*, or *cob-box*, gene), three subunits of cytochrome *c* oxidase (encoded by the *cox1*, *cox2*, and *cox3* genes) and three subunits of ATP synthase (encoded by the *atp6*, *atp8*, and *atp9* genes). The *cytb*, *cox1*, and *21S rRNA* genes contain introns, some of which are translated, independently or in frame with their upstream exons, to produce maturases (e.g., the *bl2* intron of the *cytb* gene, see [Figure 3](#)) or site-specific endonucleases (the ω intron of the *21S rRNA* gene); others encode complex proteins with multiple functions, that is, maturases, reverse transcriptases, and endonucleases (e.g., the *al1* intron of the *cox1* gene). Red: exons of protein-coding genes; blue: introns (*al1*–*al5*; *bl1*–*bl5*; ω); hatched blue: intron-encoded ORFs; green: hypothetical ORFs; yellow: 9S, 15S, and 21S rRNAs; solid circles: tRNAs. Flags indicate the transcription initiation sites and their orientation. The orientation of all the transcription units is clockwise, with the exception of the *trnA^{thr}* gene (open circle), which is transcribed from the opposite strand.

expression, as well as all other mitochondrial proteins (about 800 yeast proteins located in the organelle are currently known). These are translated in the cytoplasm and then imported into different compartments of the organelles, using protein-specific import mechanisms. During the last decade, an in-depth analysis of the messenger RNAs (mRNAs) transcribed by these nuclear genes was performed in the laboratory of Claude Jacq in Paris. They have shown that about half of these mRNAs are positioned and translated close to mitochondria, while the other half are translated on free cytosolic polyosomes. The mitochondrially localized mRNAs (MLRs) are addressed there by a targeting sequence present at the amino terminus of translated precursors (mitochondrial targeting sequence (MTS)) and by elements present in the mRNA coding sequence. As MTS is recognized by the mitochondrial

receptor–translocator TOM–TIM, which is responsible for importing protein into mitochondria, it ensues that, for these proteins, the two events, translation and import, are closely connected (co-translational import). Interestingly, MLR proteins are prevalently of prokaryotic origin and are key elements of the core construction of the molecular complexes. The peripheral proteins are instead translated on free cytosolic polyosomes and then imported into mitochondria. The fraction of MLR–mRNA encoding proteins needed for mitochondrial translation and assembly of protein complexes is expressed early in mitochondrial biogenesis and depends on the translational regulator Puf3p. Instead, Puf3p-independent MLR–mRNAs, which encode structural proteins of protein complexes, are expressed successively.

General Features of Simple and Mosaic Genes

To describe the expression of yeast mitochondrial genes, we distinguish between simple genes and mosaic genes, i.e., genes containing introns and thus subject to a more complicated expression pathway.

Transcription

The yeast mitochondrial genome is ~4 times larger than mammalian mitochondrial genomes, although they contain approximately the same number of genes. The difference is due to the lengths of intergenic regions and to the presence of introns in some of the yeast genes. Whereas the 16 000-base-pair mammalian mitochondrial genome is transcribed by two opposite promoters (one for each strand), genes on the 80 000-base-pair yeast mtDNA are transcribed, singly or in clusters, from several promoters (14 active promoters have been identified, see [Figure 1](#)). The consensus sequence of mitochondrial promoters is a nonanucleotide 5'ATATAAGTA 3', whose last A is the +1 position of the transcript, and termination of transcription is indicated by the dodecanucleotide consensus 5'AAUAAUUAUCUU 3' (see [Figure 2](#)).

As in the case of bacterial transcription, all mitochondrial genes are transcribed by the same RNA polymerase. This is composed of only two nuclear-encoded subunits, a core RNA polymerase, Rpo41p, which is similar to the very simple T-odd phages RNA polymerases, and the mitochondrial transcription factor, Mtf1p, which is required for the recognition of the promoter by the holoenzyme and is released when Rpo41p enters into the elongation mode, as occurs for sigma factors of bacterial RNA polymerases. Mtf1p, in fact, shares sequence similarity with regions 2 and 3 of bacterial sigma factors, but, unexpectedly, crystal structure of Mtf1p has revealed clear similarity to the family of dimethyladenosine methyltransferases, and one of the two human homologs of Mtf1p has been proved to possess RNA methyltransferase activity. This is one of the several evidences where the structure/function relationship of a present-day protein indicates that it might have evolved from a multifunctional ancestor or from a protein with a different function.

At least two additional factors, Nam1p (Mtf2p) and Sls1p, interact with the amino-terminal domain of mitochondrial RNA polymerase: these are also involved in posttranscriptional processing and in translation, thus allowing the coordination of transcription with the subsequent events.

Figure 2 Main features of the expression of a simple mitochondrial protein-coding gene. The open reading frame (ORF) of the gene located in the mtDNA is transcribed into messenger RNA and translated into a polypeptide chain according to the general principles of molecular biology. However, most of the elements of these two machines derive their information from a different cellular compartment than the one where these processes take place. The genes coding for the transcriptional machinery as well as those involved in the processing or stability of mRNA are located in the nucleus, the proteins synthesized in the cytoplasm and imported inside the mitochondrion where they recognize specific signals, that is, mtDNA or mtRNA sequences or structures indicating the beginning and the end of DNA transcription or RNA processing (e.g., Mtf1 and Nam1). The next step of gene expression is even more complex, since in addition to numerous nuclear genes coding for proteins involved in initiation/termination of translation, as well as the translation process itself (more than 70 ribosomal proteins, e.g., Nam9, all translation factors, e.g., Cbp1, and all specific mitochondrially located tRNA synthetases), a number of genes located in the mitochondrial genome participate in the process. They encode essentially the catalytic RNAs: the two, large and small, rRNAs, the complete set of tRNAs, and a subunit of RNase P. As a result of this double inheritance scenario, a mutational lesion in any one of the elements (e.g., the nuclear-encoded leucine tRNA synthetase by gene NAM2 or a mtDNA-encoded tRNA) will ineluctably and irreversibly abolish the expression of all the genes located in mtDNA.

RNA Processing: 5' and 3' Processing

Mitochondrial transcription units are unusual as they are characterized by the presence of mRNAs interspersed with tRNA and rRNAs. In human mtDNA tRNAs genes 'punctuate' the very long principal transcription unit and their processing at both ends 'releases' the majority of other RNAs. In yeast, the mitochondrial transcription units not only are shorter but also contain various combinations of RNAs. tRNA precursors are processed at 5' end by mitochondrial RNase P and at 3' end by a specific endonuclease (successively tRNAs are matured by CCA addition and nucleotide modifications). The processing of mRNAs at their 5' end consists of a cleavage to generate mature mRNA at a position specific for each transcript. In some transcription units, the transcript is first released by the 3' end processing of a preceding tRNA or mRNA and then processed by nuclear-encoded factors (e.g., Pet127p and Cbp1p for the cytochrome *b* transcript). Processing at 3' end of mRNAs is done near the conserved dodecamer sequence 5'AAUAAUUAUUCUU3', which is protected by a complex of three proteins before cleavage by a probably specific endonuclease. All these processes are assisted by several nuclear-encoded proteins with a gene-specific or a more general role (see Figure 2).

The correct expression of the yeast mitochondrial genome depends on the balance between transcription and RNA

degradation. The mitochondrial degradosome complex (mtEXO) is composed of a helicase (Suv3p) and an exoribonuclease (Dss1p) that together create an adenosine triphosphate (ATP)-dependent 3'-to-5' exoribonuclease activity.

Processing of Mosaic Genes Is More Complex: RNA Splicing

A typical feature of yeast mtDNA, which is not shared by human mtDNA (but is common to many mtDNA from plants, fungi, and protists), is that some of its genes are split by introns. In *S. cerevisiae* these are the 21S rRNA, *cytb* (*cob-box*), and *cox1* genes. Splicing of these introns is catalyzed by the intron itself (catalytic RNA or ribozyme), and depends on the formation of a conserved RNA three-dimensional structure, which enables them to undergo self-splicing *in vitro*, albeit inefficiently and only under nonphysiological conditions. *In vivo*, however, splicing requires the presence of specific proteins that function to promote a stable and active RNA conformation. Furthermore, some yeast mitochondrial introns behave as mobile genetic elements, as they can be inserted into an intronless version of the gene at the same position it already occupies in the intron-containing version (intron homing) or to a novel location (intron transposition). Mitochondrial introns belong to two classes, group I and II, based on the secondary and tertiary structure of the intron transcript and on the mechanism of splicing. The mechanism of splicing

of group II introns has suggested that they might be progenitors of nuclear pre-messenger introns and of the spliceosome-catalyzed splicing process, with group II intron domains having evolved into small nuclear RNAs (snRNAs).

Several features of mitochondrial introns have been uncovered in the laboratory at Gif-sur-Yvette in the late 1970s; among these, some encode proteins, that is, RNA maturases, which assist the splicing of the intron itself and sometimes also of a different intron (see Figure 3), besides promoting intron mobility. Intron-encoded proteins also belong to two groups. Group I proteins are members of the LAGLI-DADG family of DNA endonucleases (characterized by the presence of the conserved amino acid motif LAGLIDADG) and, besides the endonuclease activity required for intron mobility via DNA (as occurs for prokaryotic transposons), some of them have high-affinity RNA-binding properties necessary for their role in splicing. Mobile group II introns (e.g., intron aI1 of the *cox1* gene) not only encode multifunctional proteins, endowed with maturase and DNA endonuclease activity, but also encode reverse transcriptases that bind specifically to the intron RNAs to promote both intron mobility and RNA splicing. In the case of group II introns, transposition occurs via RNA, the procedure adopted by eukaryotic nuclear retrotransposons and retroviruses. Some of the mitochondrial intron-encoded proteins are translated in-frame with the upstream exon and

subsequently processed to mature proteins by various proteases. This process shows how the different events of mitochondrial gene expression (in this case, splicing and translation) are strictly interconnected and also enlightens a peculiarity of mitochondrial translation, that it starts immediately after transcription, as in prokaryotes, however before RNA processing, an occurrence unique to this system.

In vivo self-splicing of yeast mitochondrial introns is thus assisted by proteins that, in general, have the role to promote the folding of the catalytic core of the intron, inducing the formation of nucleotide interactions required for catalytic activity. These proteins are the maturases encoded by the intron itself and other proteins, encoded in the nuclear genome, that concur in assisting the splicing event. Many of these proteins have been identified as suppressors of splicing-defective mitochondrial mutations and most of them are proteins that, besides their role in mitochondrial splicing, have also other functions. An example is the mitochondrial enzyme leucyl-tRNA synthetase, Nam2, which is also necessary for the splicing of several group I introns, as it recognizes conserved tRNA-like structural features of the intron RNA. Another example is the Mss116p DEAD box protein, an RNA chaperone with helicase activity, which is required both for efficient splicing of all group I and II introns and for translation activation. The Mrs2 protein, which assists splicing of group II introns, has

Figure 3 Specific features of the expression of a mosaic mitochondrial protein-coding gene. Several yeast mitochondrial genes contain introns and some of these introns contain ORFs (see Figure 1). The expression of such mosaic genes occurs in two successive steps supplementary to the general features of expression of simple genes (see Figure 2). The primary, unspliced RNA transcript (pre-mRNA) for apocytochrome *b* acts as a messenger for a protein translated from the upstream exon ORF of cytochrome *b* and the ORF of the successive intron. This fusion protein, mRNA maturase (in the example shown referred to as the bI4 RNA maturase), promotes catalytically the excision of the intervening sequence from the pre-mRNA and ligation of cytochrome *b* exonic RNA leading to the formation of cytochrome *b* mRNA. The maturase recognizes specific structures of the intervening sequence, helps the productive folding, and facilitates the activity of the ribozyme. At the same time, the maturase activity destroys the RNA which codes for itself and thus exerts a negative feedback for its own biosynthesis. As a consequence, the amount of maturase in the organelle is very low, and the protein can be detected only when its splicing function is impaired. Generally, the maturases act selectively on the introns which encode them. A notable exception is the maturase shown in the example, that is, the maturase encoded by the fourth intron of the cytochrome *b* gene (bI4): its activity is essential also for the splicing of the fourth intron (aI4) of a different gene, *cox1*, which encodes the subunit one of cytochrome *c* oxidase. In this manner, the expression of the key catalysts of the electron transfer cascade may be coordinated.

actually a more general function, as a mitochondrial inner membrane Mg^{2+} channel. A particularly interesting protein is Nam1, which is involved in the removal of introns from the *cytb* and *cox1* transcripts and in overall translation capacity, and is also responsible for coupling these processes to transcription, through direct interaction with the amino terminus of mitochondrial RNA polymerase, Rpo41.

Translation

Translation of mitochondrial mRNAs resembles more closely its prokaryotic than eukaryotic counterpart with respect to the spectrum of antibiotics inhibiting mitochondrial translation. Also, mitochondrial mRNAs are uncapped and lack the poly(A) tail, as prokaryotic mRNAs. However, mitochondrial translation has unique features, for example, the use of an alternative genetic code and the composition of mitochondrial ribosomes. These are made up of nuclear-encoded proteins (with the exception of Var1), the majority of which have no recognizable homology to known proteins, that is, are unique. Some of these proteins have more specialized functions connected with the coupling of the translation process to the inner mitochondrial membrane, where the seven hydrophobic mtDNA-encoded proteins have to be assembled.

The 5'-untranslated leader sequences (UTLs) of mitochondrial mRNAs contain sequence or structural signals that indicate the translation initiation site and that are recognized by mRNA-specific activator proteins (e.g., Cbp1 for *cytb*, Pet309 for *cox1*, Pet 111 for *cox2*, and Pet494p for *Cox3* mRNA). Additional general factors are involved in translation initiation, elongation, and termination. Some of the translational activators, which mediate mRNA interactions with mitochondrial ribosomes, are organized on the surface of the inner mitochondrial membrane in a way that facilitates assembly of the inner membrane complexes. Assembly of these complexes necessitates also other proteins, for example, Oxa1p ensures co-translational insertion of the nascent mitochondrial-encoded polypeptides into the membrane.

In this way, synthesis of the mitochondrially encoded proteins is coordinated with their assembly into multimeric respiratory complexes. As the latter are made up also of nuclear-encoded subunits, translation of polypeptides from both origins and their assembly into complexes must be topologically coordinated. This suggests that a process of co-translation occurs where the inner and outer membranes

are in intimate association (contact sites): actually, it has been observed that ribosomes interact with yeast mitochondria at outer-inner membrane junctions.

Glossary

Cristae The complex internal compartments of mitochondria that are formed by invagination of the inner membrane.

Crista junctions Tubular regions of the inner membrane that connect the internal cristae compartments to the region of the membrane along the mitochondrial periphery.

Electron tomography A technique involving computation of a three-dimensional density map from scores of images recorded in an electron microscope from a serially tilted specimen.

Mitochondria The organelle in eukaryotic cells, composed of an outer and inner membrane, that uses the free energy of substrate oxidation for adenosine triphosphate (ATP) production.

Mitochondrial Structure

The mitochondrion is the organelle in eukaryotic cells that is the primary generator of adenosine triphosphate (ATP), the molecule that fuels most of the cell's machinery. The chemiosmotic mechanism of ATP production involves establishment of an electrochemical gradient across the mitochondrial inner membrane by the respiratory chain complexes. The free energy in this gradient is coupled to phosphorylation of adenosine diphosphate (ADP) by the F_1F_0 ATP synthase on the inner membrane. Since chemiosmosis entails very rapid fluxes of ions and metabolites between the mitochondrial interior and the cytosol, the shape as well as the permeability properties of the energy-transducing inner membrane can be expected to affect mitochondrial function.

Electron Microscopy and the Structure of Mitochondria

Pioneering work of G Palade, F Sjostrand, and many others in the 1950s led to the first high-quality electron microscopic images of mitochondria. Controversies ensued, partly due to the inherent difficulty of interpreting images of plastic sections that were too thin (80 nm) to convey three-dimensional (3D) structure. Conversely, the section thickness imposed a lower limit on resolution in the axial direction (parallel to the electron beam) in these images. Thus, despite the general acceptance of a model by the early 1960s (Figure 1), determining the true morphology of mitochondrial membranes in 3D detail was a work in progress for several decades. An important advance was the development and maturation in the 1990s of electron tomography, which uses numerous micrographs of a serially tilted specimen to generate a 3D image (tomogram). Using high-voltage electron microscopes, this technique has been used to provide actual 3D images of mitochondria in thick plastic sections (200–1000 nm) with axial resolution on the order of 5–10 nm (Figure 2). Moreover, with computer-controlled cryo-electron microscopes, it has been possible to obtain 3D images of mitochondria in near-native, vitreously frozen state, without the chemical fixatives and metal stains employed with plastic sections. Cryo-tomograms have been obtained for intact, isolated mitochondria (Figure 3),

mitochondria in thin regions of culture cells, and mitochondria in mammalian tissue.

Mitochondrial Membranes and Compartments

The mitochondrion is composed of two nested membranes, which define three classes of compartments.

Outer membrane

The mitochondrial outer membrane is the interface between the organelle and the cytosol. It excludes proteins and other macromolecules, but is normally permeable to solutes below a molecular weight of ~2000 since it carries many copies of a pore-forming protein called 'voltage-dependent, anion selective channel (VDAC)' or 'mitochondrial porin'.

Inner membrane

The inner membrane is the site of the respiratory chain, the ATP synthase, and numerous carrier proteins such as the adenine nucleotide transporter (ANT) that exchanges ADP and ATP.

Intermembrane space

The space between the outer and inner membranes is called the 'intermembrane (or peripheral) space'. Its protein content, which is much lower than that of the matrix, includes kinases (for interconversion of phosphorylated metabolites) and cytochrome *c* (involved in both electron transfer and apoptosis).

Matrix space

The space enclosed by the inner membrane is occupied by a very dense, largely protein matrix. This compartment contains a variety of enzymes, particularly those of the Krebs cycle, along with several copies of the circular mitochondrial genome and numerous mitochondrial ribosomes. (Mitochondria synthesize a small number of respiratory chain proteins; 90% of the mitochondrial protein mass is imported from the cytosol.)

Cristae

The mitochondrial inner membrane has a much larger surface area than the outer membrane, typically by a factor of 2.5–10. There is a rough correlation between the energy demand in a

particular tissue and the inner membrane surface, for example, heart mitochondria have more inner membrane (and so more ATP-generating capacity) than liver mitochondria. The inner membrane is contained by the smaller outer membrane because the inner membrane is invaginated or involuted. The internal compartments defined by the infoldings of the inner membrane are called 'cristae' and the space they enclose is the intracristal space. The intracristal space connects to the intermembrane space through the openings of the cristae in the peripheral region of the inner membrane.

Mitochondrial Inner Membrane Topology

The early model of mitochondrial structure portrayed the cristae as baffle-like folds in the inner membrane (**Figure 1**). 3D images provided by electron tomography of a wide variety of mitochondria, isolated and *in situ*, indicate a fundamentally different internal architecture. The cristae, in fact, are pleiomorphic compartments that connect to each other and to the peripheral (boundary) region of the inner membrane via narrow tubular segments (**Figure 2**). These connecting regions (crista junctions) can vary in length from a few tens to several

hundred nanometers. The shape of the connecting segments can vary from narrow cylinders with openings ~ 20 nm in diameter, to slot-like with openings of 40–100 nm or wider.

Functional Implications of the Crista Junctions

The fact that cristae open into the intermembrane space through narrow, sometimes very long tubular segments suggests that diffusion of solutes between the internal compartments of mitochondria might be restricted. This was not a concern with the early structural model, which depicted cristae as baffles with very wide openings into the intermembrane compartment. Computer simulations indicate that diffusion of ADP between the intermembrane and intracristal compartments via long, narrow tubes can cause depletion of ADP in the intracristal space and locally diminished ADP phosphorylation. Thus, the topology of the mitochondrial inner membrane may directly influence the efficiency of ATP generation by the organelle.

Cristae Junctions Form Spontaneously

Tubular crista junctions appear to be a highly conserved feature of the mitochondrial inner membrane. If they are functionally important, it is expected that their formation would be spontaneous or energetically favored. This has been demonstrated with yeast mitochondria. Starting with inner membranes unfolded by osmotic swelling, tubular junctions between cristae and the peripheral region of the inner membrane re-form over a matter of minutes following addition of osmoticant. Interestingly, the inner membranes of relic mitochondria in protozoa that lack oxidative phosphorylation fold randomly and lack tubular connecting segments.

Dynamics of the Mitochondrial Inner Membrane

Although the mitochondrial inner membrane has a high protein-to-lipid ratio and encases a dense protein matrix, it is

very plastic. The morphology of this membrane in isolated mitochondria changes readily in response to osmotic and metabolic conditions.

Osmotic Adjustments in Inner Membrane Topology

H Tedeschi and D Harris showed in the 1950s that isolated mitochondria behave as perfect osmometers over a range of osmotic conditions. The matrix volume adjusts to changes in osmotic conditions (external solute concentration) by expanding (water influx) or shrinking (water efflux). Isolated mitochondria with a shrunken matrix (caused by water efflux in response to hyper-osmotic external conditions) are said to be in the condensed conformational state (Figure 2(a)). Mitochondria with a more expanded matrix (exposed to iso-osmotic or slightly hypo-osmotic conditions) are said to be in the orthodox (cell-like) state (Figure 2(b)). Exposure of mitochondria to very hypo-osmotic media causes extreme matrix swelling and eventual rupture of the outer membrane. (The latter is considered osmotically inactive due to its permeability to small solutes.)

Changes in Inner Membrane Topology Associated with Metabolic State

In the 1960s, C Hackenbrock demonstrated that isolated mitochondria could reversibly switch between orthodox and condensed conformations during respiration. When ADP is added, respiring mitochondria change from orthodox to condensed conformation, then back to orthodox as ADP runs out. Condensed mitochondria tend to have larger internal

compartments with longer cristae junctions, which can limit ADP diffusion into the cristae. Thus, the switch to orthodox conformation (smaller internal compartments, shorter tubular junctions) as ADP levels drop may prevent intracristal depletion of ADP and so maintain more efficient ATP production. Note that cellular ADP levels are normally low and mitochondria *in situ* are usually in the orthodox conformation.

Inner Membrane Fusion and Fission

Comparison of 3D images of condensed and orthodox mitochondria suggests an important role for membrane fusion and fission in regulation of inner membrane topology. Condensed mitochondria have large cristae with multiple tubular connections (crista junctions) at the periphery of the inner membrane (Figure 2(a)). Conversely, orthodox mitochondria have predominantly smaller cristae with fewer peripheral connections (Figure 2(b)). Interconversion of these two membrane topologies cannot be achieved by simple unfolding and refolding of the inner membrane. The topologies can be reconciled by postulating that large cristae with multiple tubular segments form by fusion of individual smaller cristae that make contact during matrix contraction. Likewise, matrix expansion and associated lateral stress on the inner membrane may trigger fission of larger cristae into individual tubular membranes. Note that, in tomographic images of frozen-hydrated mitochondria, large cristae clearly appear to be composed of fused tubular membranes (Figure 3). Mitochondria contain several classes of proteins that regulate outer and inner membrane dynamics, curvature and tethering during fusion and fission of the organelles. One is the dynamin-like protein Opa-1 (called ‘Mgm-1’ in yeast) which has been shown to be required not only for mitochondrial fusion but also for maintaining normal crista structure. Thus, crista morphology likely reflects a balance between inner membrane fusion and fission regulated by Opa-1 and similar proteins.

Role of ATP Synthase in Shaping the Inner Membrane

ATP synthase is a multimeric inner-membrane motor that uses the free energy stored in the proton gradient across the inner membrane to drive phosphorylation of ADP. ATP synthase has the property of forming dimers, which can associate laterally to form dimer ribbons. Mutation or knockdown of proteins involved in ATP synthase dimerization result in mitochondria that lack normal cristae with tubular junctions. High-resolution electron microscopy of isolated ATP synthase dimers and inner membrane fragments suggests that the dimer ribbons impart the curvature in the inner membrane responsible for forming narrow tubular regions, first proposed by R Allen using scanning electron microscopy.

Functional Changes in Inner Membrane Topology

In functionally intact mitochondria, inner membrane shape is not random. It is regulated by proteins, such as Opa-1 and ATP synthase subunits, and it responds to metabolic state. Several other examples of function-linked changes in the shape

of the mitochondrial inner membrane are described below. The emerging hypothesis is that mitochondrial inner membrane topology is a parameter regulated by the cell to optimize mitochondrial function in response to metabolic signals and stresses.

Crista Dilation and Oxidative Stress

Inner membranes of mitochondria in steroidogenic tissues like adrenal glands undergo a rapid transition from lamellar compartments (with typical crista junctions) to parallel arrays of dilated tubular membranes (2–3 times wider than the junctions) upon activation of the P450 hydroxylation system. A similar crista transition to extended dilated tubes is observed in flight muscle mitochondria of *Drosophila* after exposure to hyperoxic conditions. An even more drastic transition is induced by fasting in the amoeba, *Chaos carolinensis*, with the mitochondrial inner membrane converting from narrow tubes to an interconnected labyrinth of wide internal compartments displaying cubic crystalline order. These three very disparate systems have two things in common. In each case, membrane remodeling is associated with increased free radical production (oxidative stress), and the resulting membrane topology would ameliorate potential damage to the mitochondria. Wider intracristal compartments enhance internal diffusion and efflux of toxic radicals from the mitochondrial interior, while increasing the radius of curvature of membranes inhibits oxidation of lipid acyl chains by oxygen radicals.

Cytochrome *c* Release during Apoptosis

The process of apoptosis, or programmed cell death, in many cell types requires release of mitochondrial factors, including cytochrome *c*, to activate caspases involved in cellular degradative reactions. This release of mitochondrial proteins involves members of the Bcl-2 family of proteins known to regulate apoptosis, as described by S Korsmeyer and others. Truncated Bid (tBid) triggers migration of Bax from the cytosol to the mitochondrial surface, where it oligomerizes and creates large pores (by an as yet undefined mechanism) through which the proteins diffuse. Mitochondrial fragmentation (fission) occurs later in apoptosis, associated with loss of Opa-1. Not only does tBid trigger outer membrane permeabilization, but it also induces (in isolated liver mitochondria) a dramatic remodeling of the topology of the inner membrane that correlates with increased accessibility of cytochrome *c* to the intermembrane space and its more complete release. Inner-membrane curvature is locally reversed and crista junctions widen into long slots, which could expedite release of cytochrome *c* from the cristae. The topological change reflects a fundamental alteration in molecular organization of the inner membrane induced by interaction of tBid with cardiolipin. This interaction also reduces low-affinity cytochrome *c* binding to the

inner membrane surface, which would also enhance cytochrome *c* mobilization and release.

This article is a revision of the previous edition article by Ferdinando Palmieri and Martin Klingenberg, volume 2, pp. 725–732, © 2004, Elsevier Inc.

Glossary

Electrogenic, electrophoretic transport The movement of a net electrical charge across the membrane coupled to the transport of metabolites. It is driven by the membrane potential.

Exchange carriers Carriers that catalyze transport only by counter-exchange of solutes across the membrane.

Mitochondrial carriers Proteins mostly located in the inner mitochondrial membrane which catalyze transport of metabolites between cytosol and mitochondrial matrix space.

Introduction

Mitochondrial carriers (MCs) are a large family of membrane-embedded proteins that are mostly localized in the inner membrane of mitochondria. Given that this membrane is highly impermeable and only some uncharged molecules, such as O₂ and CO₂, pass through in a non-protein-mediated manner, MCs provide a link between metabolic reactions occurring in the cytosol and the mitochondrial matrix by catalyzing the translocation of numerous solutes across the membrane. Because mitochondria and cytosol cooperate in a large number of metabolic cellular processes due to enzyme compartmentalization, a continuous and highly diversified flux of solutes into and out of mitochondria takes place across the inner membrane. Indeed, MCs are involved in many important metabolic pathways such as oxidative phosphorylation, the citric acid cycle, fatty acid oxidation, amino acid degradation, gluconeogenesis, lipogenesis, transfer of reducing equivalents, urea synthesis, replication and repair of mitochondrial DNA, mitochondrial RNA and protein synthesis, heme biosynthesis, and ketone body production and utilization (Figure 1).

All mitochondrial proteins transporting metabolites (i.e., MCs) share common structural features and belong to a protein family known as the mitochondrial carrier family (MCF). This family, which is probably the largest of the solute carrier families, can be subdivided into groups according to their substrate specificity: carriers for nucleotides, carboxylates and keto acids, amino acids and other substrates; each group can be subdivided into several subfamilies. With a few exceptions, these subfamilies are widespread in the eukaryotic kingdom indicating that they play a role that has been conserved throughout the evolutionary process. The substrates transported by the MCF vary widely not only in their structure but also in their size from the smallest, H⁺, to the largest and most highly charged solutes translocated across membranes, such as nicotinamide adenine dinucleotide (NAD⁺) or coenzyme A. Most of the substrates are negatively charged, but some are positively charged or zwitterions at physiological pH values. Several MCs have isoforms encoded by different genes and others, like the human phosphate carrier, have isoforms generated by alternative splicing. The level of MC expression is greatly variable in unicellular organisms depending on the metabolic environmental conditions. In animalia and plants some MCs,

or one of their isoforms, if any, are widely distributed in all or nearly all tissues, whereas others are tissue specific and their limited distribution reflects their importance in special functions. Furthermore, given that MCs are nuclear-coded proteins they must be imported into the inner mitochondrial membrane. However, unlike most nuclear-coded mitochondrial proteins, MCF members contain targeting information in their mature sequence. Indeed, only a minority of MCs possess cleavable presequences which are not essential for targeting and probably fulfill other functions, that is, provide a binding site for chaperone heat-shock cognate Hsc70 (the phosphate carrier) or act as an internal chaperone (citrate carrier). Finally, the MCF is not restricted to mitochondria. Some MCs are localized in other cell organelles, such as peroxisomes and chloroplasts.

The aim of this concise review is to provide a comprehensive reference source of current knowledge on the structure, function, and evolution of the MCs as well as on their associated diseases.

Structure

All MCF members of known function have common structural characteristics which are different from those of any other transporter family. A unique feature of all MCs is their tripartite structure, that is, they consist of three tandemly repeated homologous domains about 100 amino acids in length. Each repeat is comprised of two transmembrane α -helices connected by an extensive polar loop exposed on the matrix side of the inner mitochondrial membrane, and the three repeats are linked by two shorter loops exposed on the cytosolic side. Therefore, a typical MC has six α -helices traversing the membrane linked by hydrophilic loops with both the N- and C-termini on the cytosolic side. Furthermore, each repeat contains a signature sequence motif PX[D/E]XX[K/R]X[K/R] (20–30 residues) [D/E]GXXXX[W/Y/F][K/R]G. Unlike the majority of the MCF members, some MCs have long extensions at the N-terminus. In particular, the Ca²⁺-binding aspartate/glutamate and adenosine triphosphate (ATP)-Mg/Pi subfamilies have an extensive N-terminal domain (more than 150 amino acids), which usually contains three or four EF-hand Ca²⁺-binding motifs and fulfills a regulatory function.

Until now, the only three-dimensional (3D) MC structure is that of the adenosine diphosphate (ADP)/ATP carrier in

Figure 1 Metabolic roles of mitochondrial carriers. The scheme does not include all of the carriers listed in Table 1 and does not show all the metabolic pathways in which individual carriers are involved (see Table 1). Abbreviations as in Table 1.

complex with its powerful inhibitor carboxyatractyloside. Basically, this structure is composed of six transmembrane α -helices (H1–H6) and three short α -helices (h12, h34, and h56) located on the matrix side and parallel to the membrane plane. H1–H6 line a funnel-shaped cavity (occupied by the inhibitor) which is open toward the cytosol and closed on the matrix side by a salt-bridge network formed by the charged residues of the first part of the three signature motifs, PX[D/E]XX[R/K]. This structure (1) exhibits a threefold pseudo-symmetry in line with the threefold sequence repeats; (2) roughly corresponds to the 'c' (cytosolic)-state of the ADP/ATP carrier (with the cavity open toward the cytosol), as carboxyatractyloside is a high-affinity ligand that binds the carrier from the cytosolic side of the membrane; and (3) based on the significant sequence conservation in the MCF, most likely represents the common folding of all the other MCF members and has therefore been used as a template for building homology models of various carriers. Furthermore, the ion-pair network mentioned above constitutes the gate of MCs on the matrix side (Figure 2(a)).

Recently the MC threefold pseudo-symmetry has been further exploited principally by Dr. E. Kunji and co-workers. The analysis of inter-repeat multiple sequence alignment of MCs of known function (substrate specificity) highlighted

symmetry-related triplets formed by the aligned residues of each carrier (see Figure 3). These triplets can be either symmetric, consisting of three identical amino acids, or asymmetric, consisting of different amino acids. Symmetric triplets are important for structure and/or the transport mechanism, while asymmetric triplets are important for recognition and/or binding of the substrate (which usually has an asymmetric distribution of functional groups). Typical symmetric triplets (30 and 33 in Figure 3) include the negatively and positively charged residues involved in the matrix salt-bridge network or matrix gate (formed by the charged residues of the sequence motif PX[D/E]XX[K/R] localized at the C-terminus of the odd-numbered transmembrane α -helices). Other symmetric triplets (93 and 96 in Figure 3), though less conserved, are the charged residues of the [F/Y][D/E]XX[R/K] motif localized at the C-terminus of the even-numbered transmembrane α -helices. These residues would form a salt-bridge network on the cytosolic side which would close the carrier in the 'm' (matrix)-state (with the cavity open toward the matrix) constituting the gate of MCs on the cytosolic side (Figure 2(b)). Typical asymmetric triplets (80 and 81 in Figure 3) are the two residues of the three even-numbered transmembrane α -helices that have been proposed to form the contact points I, II, and III of MCs for their substrates. Based on the 3D structure of the ADP/ATP

Figure 2 Structural properties of MCs. (a) Matrix salt-bridge network constituting the matrix gate of MCs. The salt bridges are formed by the positive and negative residues of the signature motifs PX(DE)XX(RK) located at the C-terminus of the three odd transmembrane α -helices. This gate closing the carrier cavity on the matrix side is documented by the 3D structure of the carboxyatractyloside-inhibited ADP/ATP carrier. (b) Cytosolic salt-bridge network constituting the cytosolic gate of MCs. The salt bridges are formed by the charged residues of the motifs [F/Y][D/E]XX[R/K] located at the C-terminus of the three even transmembrane α -helices. This network closing the carrier cavity on the cytosolic side has been hypothesized by Dr. E.R.S. Kunji and co-workers. (c) Top view from the cytosolic side of the structural homology model of the yeast oxaloacetate/sulfate carrier (Oac1p) highlighting the carrier substrate-binding site. Transmembrane α -helices are colored as follows: H1, red; H2, tan; H3, green; H4, emerald-green; H5, cyan; and H6, blue. The residues (V37, Y93, A143, R200, A244, and R294) of the six transmembrane α -helices protruding into the cavity at the height of the binding site and the substrate α -isopropylmalate are shown in stick representation using the VMD color code: cyan, C-atoms; red, O-atoms; white, H-atoms; and blue, N-atoms. Possible interactions between the substrate and residues (V37, Y93, R200, and R294) are highlighted as follows: electrostatic/polar (black dashed lines), hydrophobic (purple dashed lines) and via bridging water (orange dashed lines). (d) Lateral view of the structural homology model of human aspartate/glutamate carrier (isoform 1) highlighting the position of the conserved prolines and glycines in the even and odd transmembrane α -helices. The triplet PPP of the odd helices (no. 28 in Figure 3) and the triplet PPP of the even helices (no. 83 in Figure 3) are in purple; the triplet GGG of the odd helices (no. 19 in Figure 3) and the triplet GGG of the even helices (no. 73 in Figure 3) are in yellow. (c) Reproduced from Marobbio CMT, Giannuzzi G, Paradies E, Pierri CL, and Palmieri F (2008) α -Isopropylmalate, a leucine biosynthesis intermediate in yeast, is transported by the mitochondrial oxaloacetate carrier. *Journal of Biological Chemistry* 283: 28445–28453, with permission from The American Society for Biochemistry and Molecular Biology.

carrier, these residues protrude into the cavity of the carrier at the midpoint of the membrane one-and-a-half helix turns above the matrix salt-bridge network that closes the bottom of the cavity (Figure 2(c)). Among the three proposed contact points, point II on helix 4 is the most important because it alone can discriminate between amino acids, carboxylic acids (including keto acids), and nucleotides. In fact, point II is defined by G[IVLMT] in nucleotide carriers, by R[QHNTAV] in carboxylic acid carriers and by R[D/E] in amino acid carriers. The above-mentioned contact points constitute the common and similarly located substrate-binding site of MCs or part of it when, depending on the size, shape, and chemistry of the substrate, residues of the odd-numbered transmembrane α -helices located in the cavity at the same level and/or other residues above and below are also involved in substrate binding (Figure 2(c)). Other asymmetric triplets are, for example,

84 and 88 in the ATP-Mg/Pi carrier subfamily and 84, 85, and 88 in the aspartate/glutamate and glutamate carrier subfamilies (Figure 3).

Finally, the analysis of inter-helix multiple sequence alignment revealed first the presence of a well-conserved glycine nine residues before the prolines of the PX[D/E]XX[K/R][X/K/R] sequence motif in the odd transmembrane helices; and second, the presence of a conserved proline in the even transmembrane helices 10 residues after the glycine corresponding to the last residue of the second part ([D/E]GXXXX[W/Y/F][R/K]G) of the sequence motif (Figure 2(d)). Interestingly, the above-mentioned Gly and Pro of the odd helices are aligned with the Gly and Pro of the even helices in an antiparallel fashion. Moreover, these Pro and Gly residues are located strategically between the substrate-binding site and the gates on both sides. As documented for the Pro of the odd helices by the 3D

Figure 3 Alignment of symmetry-related amino acid triplets of representative carriers for nucleotides, amino acids and acids in *Homo sapiens*, *Saccharomyces cerevisiae*, and *Arabidopsis thaliana*. Each triplet of a single carrier is formed by the three aligned residues derived from the inter-repeat multiple sequence alignment. The triplets are ordered horizontally according to the number of the first-repeat amino acids of the bovine ADP/ATP carrier sequence (NP_777083). Only symmetry-related triplets of residues protruding into the carrier cavity are shown with the exception of triplets 19, 28, 73, and 83. ADP/ATP carriers (AAC), ATP-Mg/Pi carriers (APC), *S. cerevisiae* ATP-Mg/Pi carrier (Sal1), human FAD/folate carrier (FAD), *S. cerevisiae* FAD carrier (FLX1), *S*-adenosylmethionine carriers (SAMC), aspartate/glutamate carriers (AGC), citrate transporter proteins (CTP), oxodicarboxylate carriers (ODC), and phosphate carriers (PIC) are reported. Amino acids are colored according to the default Jalview-Zappo style.

structure of the ADP/ATP carrier, it has been proposed that the Gly of the odd helices and the Gly and Pro of the even helices can also act as hinges to open or close the carrier gate on the matrix or cytosolic side (see section **Mechanism of Transport**).

Extension of the MCF

The MCF is typified by the sequence features of its members: a tripartite structure, a threefold repeated signature motif, and six transmembrane α -helices (two in each of the three repeats) separated by hydrophilic loops. The term MCF was established after identifying its first six members, which had been purified from mitochondria. Indeed, the ADP/ATP carrier, the uncoupling protein and the carriers for phosphate, citrate, oxoglutarate/malate, and carnitine/acylcarnitines were sequenced by Edman degradation or by molecular biology techniques based on minimal protein sequence information. In the genomic era, searching genome databases using the sequence features of the MCF has revealed a large number of MCF members. For example, the genome of *Saccharomyces cerevisiae* encodes 35 MCs, that of *Arabidopsis thaliana* 58, and the *Homo sapiens* genome 53.

Approximately half of the *H. sapiens* and *S. cerevisiae* MCs have been characterized in terms of substrate specificity and kinetic parameters, in particular by transport assays upon heterologous gene expression, purification, and reconstitution into liposomes. This gene-to-function strategy was first employed for the bacterial overproduction and functional reconstitution of the bovine oxoglutarate carrier, which was indeed the first eukaryotic membrane protein to be expressed in *Escherichia coli* and renatured. In addition, for some carriers, subcellular localization, tissue distribution, and their physiological role in

cell metabolism and specialized cell functions have also been determined. Until now, 23 subfamilies of MCs have been disclosed based on substrate specificity (Table 1). Among these, the uncoupling protein subfamily has been included in Table 1 for its relevance, although the substrate specificity of several of its members is yet to be determined. Furthermore, MC subfamilies are characterized by specific sets of symmetry-related triplets (Table 1 and Figure 3). For example, all the members of the ADP/ATP carrier subfamily exhibit triplets 11 (DNS), 19 (AGT), 23 (KL[G/S]), 84 (TYG), 85 (QRX), and 88 (NYV), as well as all the members of the aspartate/glutamate carrier subfamily triplets 22 (GQA), 77 (QCR), 84 (EFQ), 85 (KSF), and 88 (KYT). Of note, related subfamilies transporting structurally similar substrates may share some characterizing triplets as well as some substrates. For example, the glutamate and aspartate/glutamate carrier subfamilies share triplets 22 and 85. Finally, the existence of subfamily-specific sets of symmetry-related triplets (Table 1) offers the possibility of predicting the function (substrate specificity) of yet unidentified carriers in different organisms.

Evolution of MCs

In agreement with the large number of MC subfamilies already identified (see above), the phylogenetic tree of all the MCs of *A. thaliana*, *H. sapiens*, and *S. cerevisiae* presented in Figure 4 shows that the MCs of these three evolutionary-distant species (146 carriers altogether) cluster into many different clades, suggesting a large variety of specialized functions. Furthermore, with a few exceptions (e.g., the guanosine triphosphate/guanosine diphosphate (GTP/GDP) carrier subfamily present only in fungi, the di-/tri-carboxylate carrier subfamily only in plants and the aspartate/glutamate carrier subfamily in fungi

Table 1 Mitochondrial carrier subfamilies defined by substrate specificity and symmetry-related amino acid triplets

Mitochondrial carrier subfamilies	Main substrates	Main metabolic roles	Characterizing triplets
1. <i>For nucleotides/dinucleotides</i>			
ADP/ATP (AAC)	ADP, ATP	Oxidative phosphorylation, energy transfer, phosphate transfer	11 (DNS), 19 (AGT), 23 (KL[G/S]), 84 (TYG), 85 (QRX), 88 (NYV)
Coenzyme A/PAP (CoC)	CoA, PAP, dephospho-CoA, ADP, ATP	Krebs cycle, fatty-acid β -oxidation, heme biosynthesis, branched-chain amino acid catabolism, urea cycle (acetylglutamate synthesis), protein acetylation, mitochondrial fatty-acid synthase	23 (K[V/A]Q), 34 (IVR), 88 triplets ([K/Q]SS)
ATP-Mg/Pi (APC)	ATP-Mg, Pi, ADP, AMP	Modulation of the matrix adenine nucleotide content, regulation of mitochondrial nucleotide-dependent enzymes	23 (RQ[Q/A]), 30 (DE[A/T/N]), 84 (EYA), 88 (KDS)
Thiamine pyrophosphate (TPC)	ThPP, ThMP, dNDP, dNTP, ADP, ATP	Regulation of mitochondrial ThPP-dependent enzymes, mitochondrial DNA synthesis	23 (R[T/S]K), 34 (IT[K/R]), 80 (L[A/T]K), 85 (GAT)
Pyrimidine nucleotides (PNC)	Pyrimidine (deoxy)nucleotides	Mitochondrial DNA and RNA synthesis and catabolism	19 (G[G/A]K), 27 (CNY), 30 ([D/E]WE), 37 (QQR), 83 ([PEP], 85 (R[I/V][S/T]))
FAD/folate	FAD, folates	Mono-carbon unit donor, redox reactions	19 (GGK), 27 (HNY), 30 (DWQ)
Adenine nucleotides in peroxisomes (ANT)	ATP, ADP, AMP	Peroxisomal fatty-acid β -oxidation	19 (SAK), 30 (DAI), 33 (KAK), 37 (QKR)
NAD ⁺ (NDT)	NAD ⁺ , (d)AMP, (d)GMP	Redox reactions, redox balance of mitochondria and chloroplasts, regulation of NAD ⁺ -dependent metabolic pathways	19 (GGK), 27 (CNY), 30 (DWE), 89 (FP[L/F])
GTP/GDP (GGC)	GTP, GDP, dGTP, dGDP	Mitochondrial protein and RNA synthesis, DNA replication and repair	22 (EGS), 23 (IEL), 84 (Q GK), 85 (RSL), 88 (KLS)
2. <i>For di-/tri-carboxylates and keto acids</i>			
Citrate (CIC)	Citrate, malate, isocitrate, <i>cis</i> -aconitate, phosphoenolpyruvate	Fatty-acid and sterol biosynthesis, histone acetylation, gluconeogenesis from lactate, isocitrate (citrate)/oxoglutarate shuttle	22 (E[A/S][S/T]), 84 (KN[S/D]), 88 (RRV)
Dicarboxylates (DIC)	Malate, succinate, Pi, sulfate, thiosulfate	Krebs cycle, gluconeogenesis from pyruvate, urea synthesis, sulfur metabolism	26 (TG[C/S]), 27 (H[N/T][S/Q/N]), 33 (K[N/M]K), 88 (RQ[I/L/T])
Succinate/fumarate (SFC)	Succinate, fumarate	Gluconeogenesis	22 (EAG), 84 (KNG), 88 (RNT)
Oxoglutarate (OGC)	Oxoglutarate, malate	Malate/aspartate shuttle, isocitrate (citrate)/oxoglutarate shuttle, nitrogen metabolism, glucogenesis from lactate	26 (VGS), 27 (QTM), 33 (KLK), 35 (RRR), 77 (GTY), 84 (YVH), 88 (RQT), 93 (TSE)
Oxodicarboxylates (ODC)	Oxoadipate, oxoglutarate	Lysine, hydroxylysine and tryptophan catabolism (and synthesis in yeast)	26 (IGS), 27 (QSL), 33 (KLK), 77 (GTY), 84 (YLH), 88 (RMT)
Oxaloacetate/sulfate (OAC)	Oxaloacetate, sulfate, thiosulfate, α -isopropylmalate	Krebs cycle, sulfur metabolism, transfer of reducing equivalents, leucine synthesis in yeast	23 (VAA), 26 (TGM), 30 (E[F/Y]D), 80 (YRR), 84 ([L/M]GH), 88 (RQ[C/S])
Di-/tri-carboxylates (DTC)	Oxoglutarate, citrate, malate, oxaloacetate, isocitrate	Fatty acid synthesis, isoprenoid synthesis, transport of redox equivalents, nitrogen assimilation	26 (IGS), 27 (QSL), 33 (KLK), 35 (RRQ), 77 (GTY), 84 (YLH), 88 (RMT), 93 ([K/R]DN)
3. <i>For amino acids</i>			
Glutamate (GC)	L-Glutamate	Urea synthesis, amino acid degradation (metabolism)	22 (GQA), 77 (NTR), 80 (LRV), 84 (EFL), 85 (KSF), 88 (KYA)
Aspartate/glutamate (AGC)	L-Aspartate, L-glutamate, L-cysteinesulfinate	Malate/aspartate shuttle, urea synthesis, gluconeogenesis, cysteine degradation	22 (GQA), 77 (QCR), 84 (EFQ), 85 (KSF), 88 (KYT)
Ornithine (ORC)	Ornithine, citrulline, lysine, arginine (histidine)	Urea synthesis, basic amino acid metabolism, polyamine biosynthesis	23 ([V/I][A/S]W) but (KSN) in <i>S. cerevisiae</i> , 26 (GL[V/C]) but (ELI) in <i>S. cerevisiae</i> , 84 (EGA), but (QAV) in AtBAC2
Carnitine (CAC)	Carnitine, acylcarnitines	Fatty-acid β -oxidation	23 (VTW), 85 (FSN)

Antiport		$2.3 \frac{RT}{F} \log \frac{[S_{1c}^-][S_{2m}^-]}{[S_{1m}^-][S_{2c}^-]} + 2.3 \frac{RT}{F} \Delta pH + \Delta \Psi$	Aspartate/glutamate
Antiport		$2.3 \frac{RT}{F} \log \frac{[S_{1c}^{4-}][S_{2m}^{3-}]}{[S_{1m}^{4-}][S_{2c}^{3-}]} + 2.3 \frac{RT}{F} \Delta pH$	GTP/GDP

Figure 5 Modes of transport catalyzed by mitochondrial carriers and their driving forces. Typical examples of reaction mechanisms and driving forces are shown. Reproduced from Palmieri F and Pierri CL (2010) Mitochondrial metabolite transport. *Essays in Biochemistry* 47: 37–52, with permission from The Biochemical Society.

of species-specific carriers in the most recent branches of the tree. These later duplications concern *A. thaliana* (and other plants) more than *H. sapiens* and *S. cerevisiae*, suggesting a greater number of specific functional requirements in plants as compared to fungi and animalia.

Concerning the early evolution of MCs, their structural features clearly indicate that they result from the tandem triplication of a primordial 100-amino-acid, two-helix domain. Moreover, given that a low-grade sequence similarity is also detectable in the two helices of each repeat, it has been hypothesized that the primordial repeat may itself have evolved by the duplication of a DNA sequence encoding a single transmembrane segment.

Modes of Transport and Driving Forces

The majority of MCs catalyze strict solute antiport (exchange) reactions (Figure 5). Some mediate uniport (unidirectional substrate transport) besides antiport, whereas the uncoupling protein catalyzes uniport as the exclusive transport mode.

Based on the electrical nature of their transport reactions, MCs can be divided into electrogenic (or electrophoretic) and electroneutral transporters (Figure 5). So far, three well-characterized carriers have been shown to be electrophoretic. The ADP/ATP and aspartate/glutamate carriers catalyze exchanges that result in a charge imbalance because they transport ADP^{3-} for ATP^{4-} and aspartate⁻ for glutamate⁻ + H^+ , respectively, across the mitochondrial membrane. The third, the

uncoupling protein, catalyzes the unidirectional transport of H^+ . Electroneutral balance can be achieved by cotransport (symport) and counter-transport (antiport or exchange) of solutes, and by uniport of electroneutral metabolites (Figure 5). In some cases, electroneutrality is imposed by simultaneous carrier-mediated H^+ movement. The carrier subfamilies for phosphate and glutamate, and in yeast for oxaloacetate/sulfate, mediate the transport of anions together with an equivalent amount of H^+ (anion/ H^+ symport), and the yeast GTP/GDP carrier exchanges GTP^{4-} plus a H^+ against GDP^{3-} . Other subfamilies catalyze an exchange of anions or cations. The oxoglutarate carrier, for instance, exchanges oxoglutarate²⁻ for malate²⁻ and the ornithine carrier ornithine⁺ for lysine⁺, arginine⁺, or an H^+ .

As their driving force, MCs utilize the concentration gradient of the transported solutes and in most cases the H^+ electrochemical potential generated across the inner mitochondrial membrane by the functioning of the respiratory chain (Figure 5). Because the electrical component of $\Delta \mu H^+$ is rather high, the electrical nature of the ADP/ATP carrier and the aspartate/glutamate carrier provides a powerful means of ejecting ATP and aspartate against the concentration gradient from the mitochondrial matrix to the cytosol. In cases of H^+ symport or H^+ exchange, the transmembrane pH gradient regulates the distribution of anionic and cationic solutes across the membrane. For example, with a higher pH value inside the mitochondria, the carrier-mediated, H^+ -compensated uptake of phosphate or glutamate is stimulated, as well as the efflux of cationic solutes such as the export of ornithine in yeast.

Figure 6 Schematic representation of the transition from the c-state to the m-state, and vice versa, which mitochondrial carriers undergo in the catalytic exchange transport cycle. Trapezoids (left) illustrate the c-state after the release of the substrate toward the cytosol (bottom) and immediately after the entry of the substrate from the cytosolic side (top); trapezoids (right) show the m-state after the release of the substrate into the matrix (top) and immediately after the entry of the substrate from the matrix side (bottom); and the two central rounded rectangles depict the transition states of the carrier with the bound substrate entered from the cytosol (top) and from the matrix (bottom). The box in the center of the carrier indicates the presence of an internal cavity without reference to its shape (which varies in the different states depicted). Green ovals and blue rectangles represent the substrate entering from the cytosol and from the matrix, respectively; solid triangles indicate closed gates, and dotted triangles open/partially closed gates. Reproduced from Palmieri F and Pierri CL (2010) Mitochondrial metabolite transport. *Essays in Biochemistry* 47: 37–52, with permission from The Biochemical Society.

Mechanism of Transport

As predicted by the single-binding center-gating pore hypothesis, MCs have only one binding site in the center of the carrier which is open alternately to the two opposite sides of the membrane, that is, either toward the cytosol in the c-conformation or toward the mitochondrial matrix in the m-conformation. In the c-state, the substrate enters the carrier from the cytosolic side and binds to the carrier (see Figure 6). As binding occurs, the protein rearranges, according to the induced transition fit theory of carrier catalysis, to attain an optimum fit between the protein and the substrate corresponding to the transition conformation. In the transition state, the substrate is bound in the cavity approximately at the center of the carrier and the carrier is compactly structured around the substrate almost entirely closed on either side of the membrane (Figure 6). The total binding energy of the optimum-fit interactions between the carrier and the substrate in the transition state triggers additional structural changes leading to the m-conformation, in which the c-gate is closed and the m-gate is opened. At this stage, the substrate which entered the carrier from the cytosolic side exits into the matrix, and the catalytic cycle continues with the entry of another substrate from the matrix (see Figure 6). This mechanism was first suggested for the ADP/ATP carrier because of the existence of high-affinity inhibitor ligands that bind to the carrier either from the cytosolic (atractyloside) or from the matrix side (bongkrekate). These ligands remove ADP or ATP and their binding is mutually exclusive, indicating a single reorienting binding site. The existence of a c-state has been demonstrated

by the crystal structure of the carboxyatractyloside-ADP/ATP carrier complex. Furthermore, the reorientation of the single binding site is supported by the common and similarly located substrate-binding site and by the kinetic ping-pong mechanism of the carnitine/acylcarnitine carrier (CAC)-catalyzed transport. Unfortunately, a 3D structure of MCs in the m-state is not yet available. Similarly, the structural changes occurring during the transition from the c- to the m-state, and vice versa, are still unknown. However, it has been proposed that they are largely due to the movements of the even and odd transmembrane α -helices (flexible hinged helix movements) consisting of a tilt of the helical segments and a kink/swivel of their termini at the level of the conservative Pro and Gly. Viewing the carrier from the cytosol, the even and odd helices would be seen rotating clockwise during the c- to m-state transition, counterclockwise during the m- to c-state transition, and vice versa, viewing the carrier from the matrix side. Moreover, during the transition from the c- to the m-state the helix termini, hinging on the Pro and Gly residues, move apart on the matrix side (opening the m-gate) and come together on the cytosolic side (closing the c-gate). The opposite movements take place during the transition from the m- to the c-state.

The above-reported mechanism describes the MC-mediated antiport mode of transport. It is thought that MCs catalyzing uniport, besides antiport, are able to undergo a reversible transition between the c-state and the m-state in the absence of the substrate. This transition requires that the activation energy barrier needed for the conformational change of these carriers be much lower than that of the obligatory 1:1 exchange carriers.

Figure 7 MC structural areas in which most transport-inactivating experimentally or naturally produced mutations are located. The 3D crystal structure of the carboxyatractyloside-ADP/ATP carrier complex (devoid of the inhibitor) is shown with the following regions in color: cytosolic gate (blue); substrate-binding site (orange); and matrix gate (purple). In P-G level 1 and P-G level 2, prolines are shown in red and glycines in yellow. Reproduced from Palmieri F and Pierri CL (2010) Structure and function of mitochondrial carriers – role of the transmembrane helix P and G residues in the gating and transport mechanism. *FEBS Letters* 584: 1931–1939.

Structure–Function Relationships

Most transport-inactivating residue replacements (with cysteine or alanine) in the oxoglutarate carrier and other MCs, as well as most missense mutations found in patients affected by MC-associated diseases (see below), are located in areas of carrier structure that are considered crucial for their function, that is, substrate-binding site, matrix gate, Pro–Gly levels 1 and 2, and cytosolic gate (Figure 7). Notably, nearly all the residues that interact with the lipid bilayer as well as the large majority of those participating in inter-helical interactions tolerate replacement with cysteine or alanine.

Diseases

The ongoing identification of MC gene function has favored the disclosure of several diseases associated with defective carriers. Until now, 11 MC-related diseases have been well characterized biochemically and genetically (Table 2). These disorders are rare errors of metabolism caused by alterations of the genes encoding MCs. The genes are essential for either oxidative phosphorylation (e.g., ADP/ATP and phosphate carriers) or other cell functions (e.g., carriers for glutamate, aspartate/glutamate, thiamine pyrophosphate, and carnitine/acylcarnitines). Therefore, the symptomatology of these diseases depends on the specific metabolism affected and its relevance in specific tissues. For example, CAC deficiency (OMIM 212138) is a fatty-acid β -oxidation disorder that

Table 2 Diseases caused by mutations in genes encoding MCs

Disease	Gene	Carrier
CAC deficiency	SLC25A20	Carnitine/acylcarnitine
AGC2 deficiency (CTLN2/NICCD)	SLC25A13	Aspartate/glutamate 2
HHH syndrome	SLC25A15	Ornithine/citrulline
adPEO	SLC25A4	ADP/ATP
Congenital Amish microcephaly	SLC25A19	Thiamine pyrophosphate
Neuropathy with bilateral striatal necrosis	SLC25A19	Thiamine pyrophosphate
AAC1 deficiency	SLC25A4	ADP/ATP
Early epileptic encephalopathy	SLC25A22	Glutamate
PiC (isoform A) deficiency	SLC25A3	Phosphate
AGC1 deficiency	SLC25A12	Aspartate/glutamate 1
Congenital sideroblastic anemia	SLC25A38	? (glycine/ALA)

adPEO, autosomal dominant progressive external ophthalmoplegia; ALA, aminolevulinic acid.

Other abbreviations as in Table 1.

manifests with life-threatening episodes of coma upon fasting, cardiomyopathy, muscle weakness, and abnormal liver function, and HHH syndrome (OMIM 238970) is a disorder of the urea cycle characterized by hyperammonemia, hyperornithinemia, and homocitrullinemia. With the exception of autosomal dominant progressive external ophthalmoplegia (adPEO, OMIM 157640), all the other diseases are inherited in an autosomal recessive manner. In addition, although the molecular defect(s) responsible for 2-oxoadipate acidemia have not yet been characterized, this disease has been suggested to be due to defective oxodicarboxylate carrier, that transports 2-oxoadipate into mitochondria, or oxoadipate dehydrogenase that oxidizes 2-oxoadipate in these organelles.

Mitochondrial Outer Membrane and the VDAC Channel

M Colombini, University of Maryland, College Park, MD, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Apoptosis A self-destruct process present in cells of multicellular organisms that eliminates cells that are damaged or no longer needed.

Mitochondrion An organelle occurring in the vast majority of eukaryotic cells that is critical for energy transduction and

metabolism. It is also semi-autonomous with its own DNA and independent reproductive rate.

Voltage-dependent anion-selective channel (VDAC)

A protein found in the outer membrane of all mitochondria. It forms large channels in this membrane allowing metabolites to cross.

Origin and Structure of the Outer Membrane

Mitochondria have most likely evolved from endosymbiotic bacteria. The outer membrane may have originated as an endosomal membrane that engulfed the original endosymbiotic bacterium or may be related to the bacterial outer membrane. Whatever its origin, structurally it is a relatively simple limiting membrane forming a continuous boundary (Figure 1). It seems to limit the boundary of the mitochondrial space and, unlike the inner membrane, maintains a fairly constant total mitochondrial volume.

Further aspects of mitochondrial structure and function vary depending on the source and, thus, most of what will be presented applies to mammalian sources.

The outer membrane interacts intimately with neighboring membranes. Rivet-like connections between the outer and inner membranes often exist and are referred to as contact sites. These are mechanically sturdy as they interfere with the experimental separation of the outer and inner membranes. These contacts are proposed to serve a number of functions including the formation of macromolecular complexes between transporters and enzymes to expedite metabolic flow. The outer membrane also interacts closely with the endoplasmic reticulum and this close apposition may be the reason for preferential transfer of Ca^{2+} from the endoplasmic reticulum to the mitochondrial matrix compartment. This has been especially well studied in the heart where changes in Ca^{2+} level on a beat-by-beat basis alter dehydrogenase activity matching cellular energy consumption. If specialized docking structures are involved in this interaction with the endoplasmic reticulum, they must be more labile than the contact sites because isolation of mitochondria from endoplasmic reticulum is quite easy.

Functions of the Outer Membrane

The outer membrane of isolated mitochondria is highly permeable to metabolites due to the presence in this membrane of large aqueous channels formed by the protein called voltage-dependent anion-selective channel (VDAC). Their similarity to channel-forming proteins in bacterial outer membranes collectively referred to as porins has led some to refer to VDAC as

mitochondrial porin. Although the permeability characteristics conferred to the outer membrane by VDAC are rather complex, physical size is a major factor. Thus, under normal conditions, the outer membrane is essentially impermeable to molecules larger than 5 kDa. This allows proteins to be sequestered in the intermembrane space, the compartment between the outer and inner membranes. This sequestration serves at least two functions. First, it localizes proteins that could diffuse away to the site where they are needed. For example, the soluble protein, cytochrome *c*, is a member of the electron transport chain and must transmit electrons between complex III and IV so that respiration may proceed. Second, the sequestration prevents proapoptotic proteins from being released into the cytosol as this would initiate programmed cell death (apoptosis). Cytochrome *c* is also an example of a sequestered proapoptotic protein. The permeability barrier to proapoptotic proteins and others of similar size is lifted under some conditions that lead to cellular apoptosis.

The permeability of the outer membrane to small molecules can be regulated resulting in the outer membrane limiting metabolite flux and, consequently, the level of metabolic activity. This regulation is probably critical to changes in cell function.

Most mitochondrial proteins and RNA molecules are synthesized in the cytosol and imported into mitochondria. The Tom complex is responsible for much of the protein import through the outer membrane. Leader sequences on the proteins are recognized by Tom and the protein is treaded through a pore in the complex and delivered to the intermembrane space where it is picked up by the Tim complex in the inner membrane for translocation through that membrane. The processing of outer membrane proteins by this complex is less clear.

Mitochondria are usually found in the portion of cells where they are needed. For example, to minimize diffusion limitations they are located close to sites of high-energy dissipation. Sometimes they need to be delivered to distal sites in a cell (e.g., from cell body to nerve terminal of a neuron or to the reproductive bud of a yeast cell). Motors located on either microtubules or actin filaments move mitochondria from one location in the cell to another. The outer membrane must provide sites of attachment for the motors that perform the translocation.

Figure 1 A drawing of the membranes and compartments of a typical small mitochondrion. Composition

The composition of the outer membrane varies somewhat depending not only on the species but also on the tissue from which it was isolated. With that caveat, it can be said that there are a number of similarities between the constituents of the outer membrane and the endoplasmic reticulum, for example, the presence of cytochromes *b* and *b₅*, antimycin-insensitive reduced nicotinamide adenine dinucleotide (NADH)-cytochrome *c* reductase, and ceramide synthase. Yet there are also many differences and the enzymes present in the two locations are usually different isoforms. Thus, the similarity may reflect similar origins but certainly these two membranous compartments are distinct.

The outer membrane also contains enzymes involved in fatty acid and phospholipid metabolism and an amine oxidase. The liver mitochondria contain a peripheral benzodiazepine receptor whose role is unclear. The membrane can also bind some kinases that are typical soluble enzymes and the binding is thought to accelerate energy transduction.

The outer membrane has a higher lipid content than the inner membrane, one more typical of other cell membranes. The lipid composition is also drastically different from that of the inner membrane, the outer membrane being rich in sterol, while the inner has higher levels of cardiolipin.

VDAC Channels in the Outer Membrane

VDAC Structure

Mitochondria from all eukaryotic kingdoms contain VDAC channels in their outer membrane. These are formed by a

Figure 2 Views of mitochondrial outer membranes and the ubiquitous VDAC channels in these membranes. (a) Electron micrographs of freeze-dried mitochondrial outer membranes with two-dimensional crystals of VDAC channels (membrane with squared edges and ordered array of particles) and without such crystals (smooth membrane with rounded edges). Outer membrane vesicles isolated from mitochondria are dried down on a surface and they form collapsed sacs. (b) A surface view of the VDAC channels obtained after computer filtration and averaging of multiple micrographs containing images of two-dimensional crystals. The yellow shows regions of elevation and the dark blue areas are the openings of the pores (holes) that are formed through the membrane. These allow the metabolites to cross the outer membrane. This figure was assembled from the work of Dr. Lorie Thomas. Reproduced from Thomas L, Kocsis E, Colombini M, et al. (1991) Surface topography and molecular stoichiometry of the mitochondrial channel, VDAC, in crystalline arrays. *Journal of Structural Biology* 106: 161–171.

single polypeptide of approximately 30 kDa and form a single large aqueous pore. In some plant and fungal mitochondria, VDAC channels form two-dimensional crystals (Figure 2), which upon further analysis reveal fundamentally cylindrical proteins forming water-filled transmembrane pathways. The wall of the channel is almost certainly a single layer of protein mainly consisting of a beta structure. Experimental evidence leads to the conclusion that the transmembrane portion consists of 1 α -helix and 13 β -strands. The surface domains (yellow regions in Figure 2) likely act as binding sites for a variety of proteins that bind or interact with the channel. Three-dimensional structures of human VDAC1 refolded from

denatured protein and solved by nuclear magnetic resonance and X-ray crystallography show 19 transmembrane beta strands and virtually no surface domains. These structures reveal a nonnative conformation as they are incompatible with numerous functional studies.

VDAC Function and Dynamics

The primary role of mitochondria is metabolism that is closely integrated with the metabolism occurring in the cytosol. This requires the continuous and rapid exchange of metabolites between these two major compartments. VDAC channels in the outer membrane can exist in conformational states that either favor or hinder metabolite flux. The state that favors metabolite flux, the open state, does so by having an electrostatic environment that favors anions. In addition, the charge distribution in the lining of the channel is such that it favors the translocation of adenosine triphosphate (ATP) over that of anions of similar size and charge. In the closed states, the water-filled channel is somewhat narrower (the pore size decreases from 2.5 nm in the open state to 1.8 nm in the larger of the population of closed states) but, most importantly, the electrostatic nature is such that it hinders the flow of anions. A positively charged region lining the channel in the open state is translocated out of the channel resulting in a pathway with a net negative charge. This excludes ATP and drastically reduces the permeability of other anionic metabolites. At the same time, this change favors the flux of cations.

This gating of VDAC is voltage dependent and, thus, the channels can respond to changes in the voltage across the outer membrane. An electrical potential across this membrane may arise from the presence of different charged macromolecules in the aqueous compartments (Donnan potential) and/or differential metabolite flux responding to metabolic rates. In addition, numerous factors influence this gating process including cytosolic NADH levels and specific proteins in the cytosol and intermembrane space. The importance of this regulation is indicated by its remarkable conservation of VDAC from all species tested (including all eukaryotic kingdoms). The diversity of influences on the gating of VDAC indicates that VDAC may integrate the influence of a variety of cellular factors and, thus, tune mitochondrial activity appropriately.

VDAC's ability to bind with cytosolic hexokinase and intermembrane space creatine kinase has been proposed to result in organized structures that increase the efficiency of energy transduction.

The Outer Membrane and Apoptosis

Apoptosis, programmed cell death, is a process by which a cell repackages itself to be ingested by other cells, generally macrophages. The outer membrane separates proteins that once combined initiate an amplification cascade leading to 'full blown' apoptosis. The leakage of proteins from the intermembrane space into the cytosol is sufficient to cause apoptosis. Even injecting just one of these proteins, cytochrome *c*, into the cytosol is sufficient.

How the outer membrane becomes permeable to proteins is an area of intense investigation. The proteins that cross this membrane can be as large as 50–100 kDa, proteins of the Bcl-2 family partition between the cytosol and the outer membrane. They can exist as both soluble proteins and intrinsic membrane proteins capable of generating ion channels. Some of these are proapoptotic and others are antiapoptotic. Some antiapoptotic proteins are often associated with the outer membrane under normal conditions, that is, cells functioning normally, and may favor normal mitochondrial function. Others translocate to the outer membrane at the early stages of apoptosis, perhaps forming the protein efflux pathways. The sphingolipid, ceramide, can also be produced in mitochondria early in the apoptotic process and has been shown to be able to form channels large enough for protein flux.

Under some conditions of apoptosis induction, exchange of nucleotides between mitochondria and the cytosol is greatly inhibited. The outer membrane becomes poorly permeable to ATP and adenosine diphosphate and other anionic metabolites. This phase precedes the release of intermembrane space proteins and in this phase cells can be rescued. This gives the outer membrane the role of deciding between life and death.

Emerging Importance of the Outer Membrane

Once considered relatively unimportant, the mitochondrial outer membrane is emerging as a site for control of overall mitochondrial function and a location where the fate of the entire cell is decided. Despite its deceptively simple appearance, this membrane performs a variety of vital functions. By hindsight, its location at the frontier between the cytosol and the mitochondrial spaces makes it an ideal site for control of the flux of matter and transduction of information.

Mitochondrial Permeability Transition Pore

P Bernardi, University of Padua, Padua, Italy

© 2013 Elsevier Inc. All rights reserved.

Introduction

The mitochondrial permeability transition (PT) can be defined as a Ca^{2+} -dependent increase of mitochondrial inner membrane permeability to solutes with molecular masses up to about 1500 Da, which has been studied mostly in mammals. *In vitro* at least, it is accompanied by depolarization, matrix swelling, depletion of matrix pyridine nucleotides (PNs), outer membrane rupture, and release of intermembrane proteins including cytochrome *c*. The PT is believed to be due to opening of a high-conductance, voltage-dependent channel in the inner mitochondrial membrane, the PT pore (PTP); in spite of many efforts, its molecular identity remains unknown. The occurrence of swelling in isolated mitochondria and its basic features (stimulation by Ca^{2+} and Pi uptake and inhibition by Mg^{2+} , adenine nucleotides, and acidic pH) had been recognized very early in studies on isolated mitochondria, as were its detrimental effects on energy conservation. As a result, the occurrence of a PT has long been considered an *in vitro* artifact of little or no physiological interest. This state of affairs was paradoxically worsened by the clarification of the basic mechanism of mitochondrial energy conservation, which took place in the 1960s and 1970s, and culminated with the award of the 1978 Nobel prize in chemistry to the late Peter Mitchell. He understood that the initial event in energy conservation is charge separation at the inner mitochondrial membrane, for which he coined the term 'chemiosmosis'.

Chemiosmosis, Mitochondrial Channels, and the PT

The four basic postulates of chemiosmosis are (1) that the membrane-located adenosine triphosphatase (ATPase) reversibly couples the translocation of protons across the membrane to the flow of anhydro-bond equivalents between water and the couple adenosine triphosphate (ATP)/(adenosine diphosphate (ADP) + Pi); (2) that the membrane-located respiratory chain catalyzes the flow of reducing equivalents, coupling reversibly the translocation of protons across the membrane to the flow of reducing equivalents during oxido-reduction; (3) that the mitochondrial inner membrane has specific carriers allowing anion- OH^- and cation- H^+ exchanges that regulate the pH and osmotic differential across the membrane, and permit the flux of essential metabolites without collapse of the membrane potential; and (4) that the systems of the first three postulates are located in a specialized coupling membrane which has a low permeability to protons and to anions and cations generally. The fourth postulate was widely (and erroneously) implied to mean that the inner membrane did not possess cation channels. Given this view, prevailing as late as the 1990s, it comes as no surprise that the PTP, at an estimated diameter of 3 nm, did not attract too much interest in bioenergetics. Things have changed dramatically over the last 15 years,

following the demonstration that the inner mitochondrial membrane does possess cation channels that are expectedly tightly regulated, and that a PT can occur in cells, tissues, and organisms where it plays a role in cell death, and possibly in Ca^{2+} homeostasis.

Molecular Nature of the PTP

Two main theories were proposed to explain the PT: the membrane theory, postulating that the permeability increase occurred mainly or exclusively in the lipid bilayer following activation of a Ca^{2+} -dependent phospholipase, and the pore theory, postulating that the PT was due to opening of a regulated proteinaceous channel. The discovery that the PTP can be desensitized by nanomolar concentrations of cyclosporin A (CsA) without any effects on phospholipase activity shifted the balance in favor of the pore theory. The effects of CsA on the PTP are mediated by its high-affinity binding to cyclophilin (CyP)-D, a matrix peptidyl prolyl *cis-trans* isomerase that assists in protein folding, and is believed to act as a promoter of the PT. CyP-D is not a structural part of the channel but rather a modulator, and the only PTP-related molecule identified so far.

CyP-D

CyP-D is part of the CyP family of proteins, which in mammals has 16 members, among which cytosolic CyP-A is the most studied. The binding of CsA to CyP-A creates a complex that acquires the ability to bind to, and inhibit, cytosolic calcineurin, a Ca^{2+} -calmodulin-dependent phosphatase that catalyzes dephosphorylation (hence nuclear translocation) of nuclear factor of activated T-cells (NFAT), an essential element for the activation of the immune response against transplants. As a result of calcineurin inhibition, CsA prevents transplant rejection. It has been established that calcineurin inhibition instead is not required for PTP inhibition by CsA.

The mechanism through which CyP-D modulates the PTP was clarified quite recently. We found that CyP-D hinders a regulatory site for matrix inorganic phosphate (Pi), whose occupancy results in PTP inhibition (rather than the activation normally caused by Pi). When CyP-D is genetically ablated, or when CsA is added to displace CyP-D from the inner membrane, the PTP is desensitized by matrix Pi resulting in a decreased probability of pore opening. It must be stressed that mitochondria from lower eukaryotes such as yeast and *Drosophila* can undergo a permeability increase that has some points in common with the PT. This PT is insensitive to CsA, but it is inhibited by Pi; thus, the finding that Pi can be a desensitizer in higher eukaryotes as well may bridge the gap between yeast and mammals.

Recent studies have addressed the regulatory interactions of CyP-D with the F_1F_0 -ATP synthase, whose catalytic part (F_1)

and lateral stalk protrude into the matrix where CyP-D is located. CyP-D interacts with the ATP synthase under mild extraction conditions, and can be cross-linked with the oligomycin sensitivity conferring protein (OSCP), b, and d subunits (i.e., with the extrinsic part of the lateral stalk). These interactions are mentioned here because binding of CyP-D is favored by Pi, while CsA can displace CyP-D from the ATP synthase. These binding changes are matched by functional changes, with a Pi-dependent decrease of specific activity that is reversed by CsA. We presently do not know whether this interesting analogy with the PTP is a coincidence, or rather reflects an involvement of the F_1F_0 ATP synthase in pore formation and/or regulation, an issue that deserves further study.

Adenine Nucleotide Translocator and Voltage-Dependent Anion Channel

The adenine nucleotide translocator (ANT) has long been considered to be the main component of the PTP, possibly in association with the outer membrane voltage-dependent anion channel (VDAC). The PTP is modulated by ligands of the ANT. Atractylate, which inhibits the ANT and stabilizes it in the so-called 'c' conformation (nucleotide-binding sites facing the cytosolic side of the inner membrane), favors PTP opening, while bongkrekate, which also inhibits the ANT but stabilizes it in the 'm' conformation (nucleotide-binding sites facing the matrix side of the inner membrane), favors PTP closure. These findings are the main basis for the suggestion that the PTP may be formed by the ANT. An alternative explanation, which is based on PTP modulation by the membrane potential (see below), is that the transitions of the ANT from the 'm' to the 'c' conformation cause large changes of the surface potential that may explain PTP opening by atractylate and its closure by bongkrekate as an indirect effect on the membrane potential. Conclusive evidence that the ANT is not essential for PTP formation was obtained in mitochondria lacking all ANT isoforms, which still displayed a Ca^{2+} -dependent and CsA-sensitive PT (indicating that the ANT is not the binding partner of CyP-D either).

The PT of mammals can be induced by relatively high concentrations of substituted maleimides (see below), but this is not observed in mitoplasts (mitochondria devoid of the outer membrane), suggesting that inner membrane permeability changes also require an intact outer membrane. The suggestion that the outer membrane protein involved in PTP formation could be VDAC was based on some striking analogies with the PTP. For example, purified VDAC incorporated into planar phospholipid bilayers forms channels with a pore diameter of 2.5–3.0 nm whose electrophysiological properties strikingly resemble those of the PTP; VDAC channel properties are modulated by many conditions that also modulate the PTP; and chromatography of mitochondrial extracts on a CyP-D affinity matrix allowed purification of VDAC and the ANT, which in the presence of CyP-D catalyzed a CsA-sensitive permeabilization of liposomes to solutes. However, recent results obtained in mitochondria from mice lacking the major VDAC isoform (VDAC1), as well as from mammalian cells where all three VDAC isoforms had been deleted, indicate that each VDAC isoform is dispensable for occurrence of the PT,

demonstrating that VDACS cannot be essential components of the PTP.

Regulation of the PTP

Divalent Cations

Matrix Ca^{2+} is perhaps the single most important factor required for PTP opening. Ca^{2+} is best defined as a permissive factor, in the sense that although a PT is not observed in the absence of matrix Ca^{2+} , Ca^{2+} alone is not sufficient to induce PTP opening. Ca^{2+} is unique because all the other Me^{2+} ions that are transported by the mitochondrial Ca^{2+} uniporter (and hence can be accumulated in the matrix, such as Sr^{2+} and Mn^{2+}) are inhibitors of the PT, perhaps by competing with Ca^{2+} for the same binding sites. It has always been difficult to separate the PTP-inducing effects of Ca^{2+} from those of Pi (and possibly also of polyphosphate generated in the matrix) because the uptake of Pi (or of other species able to buffer matrix pH such as acetate or bicarbonate) is required for the uptake of substantial amounts of Ca^{2+} . The inducing effect of Pi is surprising because it should decrease free matrix $[Ca^{2+}]$; however, the effect could rather be due to the Pi-dependent decrease of free matrix $[Mg^{2+}]$, which at variance from Ca^{2+} inhibits the PTP (although Mg^{2+} is not transported rapidly across the inner membrane, it is present in substantial amounts in the matrix space). An external Me^{2+} -binding site has also been found. All tested Me^{2+} ions, including Ca^{2+} itself, cause a decreased probability of PTP opening through this site.

Proton Electrochemical Gradient

The PTP behaves as a voltage-gated channel, with an increase of the open probability as the membrane potential difference (negative inside) becomes less negative, that is, as the inner membrane depolarizes. The threshold voltage for PTP opening is affected by a variety of factors such as Ca^{2+} , Mg^{2+} , and adenine nucleotides; redox effectors including quinones; and amphiphilic molecules such as fatty acids. The existence of a voltage sensor has been postulated, which would detect the membrane potential at which opening occurs. Thus, PTP opening can be the consequence of depolarization (when the membrane potential drops below the threshold) or its cause (when effectors move the threshold toward the resting potential). The effects of the ANT inhibitors atractylate (PTP opening) and bongkrekate (PTP closure) can be easily explained within the framework of the voltage dependence. Indeed, the ANT 'c' conformation (stabilized by atractylate) neutralizes surface positive charges on the outer surface of the inner membrane, thus simulating a depolarization affecting the putative voltage sensor as a signal for PTP opening; conversely, the ANT 'm' conformation (stabilized by bongkrekate) increases the surface negative charges on the inner side of the inner membrane, thus simulating a hyperpolarization affecting the sensor as a signal for PTP closure.

The PTP is also profoundly affected by changes of matrix pH, with an optimum at $pH \approx 7.3$. Lower pH values decrease the PTP open probability via reversible protonation of histidyl residues, and higher pH values decrease pore opening via an undefined mechanism. It appears to be possible that the

inducing effect of Pi may partly depend on matrix pH buffering, as the pK_a of the $H_2PO_4^- \leftrightarrow H^+ + HPO_4^{2-}$ reaction is 7.2.

Redox Sensitivity

An important feature of the PTP is its modulation by redox effectors, a more oxidized state favoring PTP opening. This effect is conferred by at least three redox-sensitive sites that could be distinguished by a careful dissection of their regulatory factors and inhibitor sensitivity. The first is a sulfhydryl (SH) site accessible from the matrix, which is in apparent redox equilibrium with glutathione and can be blocked by low micromolar concentrations of *N*-ethylmaleimide (NEM) and monobromobimane but not by impermeant bimanes or by β -hydroxybutyrate. The second is a site of unknown chemical nature also accessible from the matrix and in apparent redox equilibrium with pyridine nucleotides, which can be blocked by NEM or β -hydroxybutyrate but not by monobromobimane. The third site is an external thiol (accessible from the intermembrane space) that undergoes oxidation and triggers PTP opening after a separate site has reacted with millimolar concentrations of NEM or low micromolar concentrations of copper-*o*-phenantroline. This complex array of PTP redox-sensitive sites has recently been confirmed by careful studies based on PTP inactivation/reactivation by photoradiation after loading mitochondria with hematoporphyrin, which induces a photodynamic effect in close proximity to the hematoporphyrin-binding sites.

Consequences of PTP Opening

The primary consequence of PTP opening is depolarization, which is followed by equilibration of ions and solutes with molecular mass below the pore cutoff of about 1500 Da. PTP opening *in vitro* is followed by release of matrix Mg^{2+} and of adenine and pyridine nucleotides, which will tend to stabilize the pore in the open conformation. PTP closure (e.g., by the addition of Ca^{2+} chelators) is followed by mitochondrial resealing and repolarization, indicating that no permanent changes of inner membrane permeability occurs as a consequence of a PT.

Matrix swelling follows stable PTP opening *in vitro*, and this can lead to damage the outer membrane with release of cytochrome *c* and other pro-apoptotic factors. Swelling results from solute and water flux to the matrix when there is an osmotic imbalance, and it can be prevented if the incubation medium contains low concentrations of pore-impermeant solutes such as polyethylene glycol 3400. Partial swelling may occur for very short PTP open times, which causes widening of the intracristal junctions that otherwise limit the diffusion of the bulk of cytochrome *c* to the intermembrane space. This event may contribute to release of cytochrome *c* through channels formed by activated Bak and Bax even when the outer membrane is intact. Mitochondria are able to shrink and fully recover energy-linked functions even after PT-dependent large-amplitude swelling with outer membrane rupture in saline media, provided cytochrome *c* is added back.

Occurrence of a PT causes secondary consequences on respiration. The initial uncoupling (due to the loss of membrane permeability) is followed by respiratory inhibition because

matrix pyridine nucleotides are readily lost at the onset of the PT. The extent of respiratory inhibition will then depend on the extent of matrix pyridine nucleotide depletion and subsequent hydrolysis by intermembrane glycohydrolase. Finally, the collapse of Δp caused by the PT will curtail ATP synthesis as long as the pore is open. Mitochondria will actually become consumers of any available glycolytic ATP, because in the absence of a proton gradient the ATP synthase will work in reverse as an ATP hydrolase. Imbalanced ion homeostasis (Ca^{2+} in particular), volume dysregulation, and cytochrome *c* release are all factors that favor cell death, as we will further discuss below.

A Role for the PTP in Cellular Ca^{2+} Homeostasis?

In respiring mitochondria, Ca^{2+} is taken up through a channel (the mitochondrial Ca^{2+} uniporter, MCU) which equilibrates the Ca^{2+} gradient with the membrane potential. The driving force is enormous, as for a voltage of -180 mV the predicted accumulation ratio at equilibrium would be 10^6 , with a matrix concentration of 0.1 M for a resting cytosolic $[Ca^{2+}]$ of 0.1 μ M. Equilibrium is never achieved because of the operation of 2 Ca^{2+} efflux pathways, the Na^+ - Ca^{2+} and H^+ - Ca^{2+} antiporters. Coupling of electrophoretic Ca^{2+} uptake via the MCU with Ca^{2+} efflux on the antiporters allows fine regulation of matrix and cytosolic Ca^{2+} (Figure 1). It should be noted that energy is required both for Ca^{2+} uptake and for Ca^{2+} release, owing to the electrophoretic nature of transport via MCU and to the fact that the stoichiometry of the antiporters is most likely $3Na^+$ (H^+) per Ca^{2+} . Operation of the antiporters is therefore favored by the membrane potential (and by the Na^+ , H^+ , and Ca^{2+} concentration gradients). As a result of this complex arrangement steady-state extramitochondrial $[Ca^{2+}]$ can be increased (and matrix $[Ca^{2+}]$ decreased) by increasing the activity of the antiporters, by decreasing the activity of the MCU, or both. Yet, the rate of uptake increases very steeply with extramitochondrial $[Ca^{2+}]$, reaching a V_{max} as high as 1400 nmol $Ca^{2+} \times mg$ protein $^{-1} \times min^{-1}$; while the maximal rate of operation of the combined antiporters is about 20 nmol $Ca^{2+} \times mg$ protein $^{-1} \times min^{-1}$. This situation exposes mitochondria to the deadly risk of Ca^{2+} overload and calcification, which can be prevented by PTP openings of short duration that have been documented in intact cells and organs. But why should have nature designed a high-conductance, apparently unselective channel for mitochondrial Ca^{2+} release? Can fast Ca^{2+} release rather occur via the MCU after depolarization?

Even after complete mitochondrial depolarization, Ca^{2+} efflux down its concentration gradient via a selective channel (like the MCU) is opposed by the buildup of a Ca^{2+} diffusion potential which, according to the Nernst equation, is -30 mV per decade. Since the inner membrane has a very low permeability to charged species (Mitchell's fourth postulate), the rate of Ca^{2+} efflux would be extremely slow and could only be increased by independent modulation of membrane ion permeability. A pore of large size like the PTP confers the obvious advantage of charge compensation within the channel itself, allowing maximal Ca^{2+} flux (i.e., at zero potential). Thus, a pore of large size would permit fast Ca^{2+} release even for very small $[Ca^{2+}]$ gradients. Since no K^+ and Na^+ concentration

Figure 1 Possible role of the PTP in cellular Ca^{2+} homeostasis. (a) Owing to the low permeability of the inner membrane to charged species and solutes, under basal conditions (when the permeability transition pore, PTP, is closed) the proton-pumping activity of the respiratory chain (RC) creates a proton electrochemical gradient whose membrane potential component (depicted as a darker matrix space) represents a powerful driving force for Ca^{2+} accumulation through the Ca^{2+} uniporter (MCU). In spite of the enormous capacity of MCU, Ca^{2+} flux is slow because the resting Ca^{2+} in the cytoplasm and intermembrane space is well below the K_m of the MCU. In spite of their low combined $V_{\max}$ (two orders of magnitude lower than that of the MCU) the Na^{+} - Ca^{2+} exchanger (NCLX) and the putative H^{+} - Ca^{2+} exchanger (HCE; the depicted stoichiometry is tentative, but operation of this efflux system is favored at high membrane potential) are adequate to prevent matrix Ca^{2+} overload, and Na^{+} accumulation is prevented by the Na^{+} - H^{+} exchanger (NHE). (b) When efflux on the NCLX and HCE is saturated (e.g., following a large Ca^{2+} discharge from the sarcoplasmic reticulum) the matrix Ca^{2+} concentration rises and causes transient opening of the PTP with depolarization and Ca^{2+} release, which is followed by PTP closure and repolarization (back to (a)). (c) For long-lasting PTP openings depolarization is no longer reversible, and solute flux through the pore leads to matrix swelling and to release of intermembrane pro-apoptotic factors which can lead to cell death. For further explanation, see text. The solid lines depict the inner membrane, while the dashed lines represent the outer mitochondrial membrane, which has been drawn at a distance from the inner membrane only to accommodate the lettering.

gradients exist across the inner membrane, PTP opening can lead to selective Ca^{2+} release without major consequences on K^{+} and Na^{+} homeostasis. In this respect, the PTP would be similar to the Ca^{2+} release channel of the sarcoplasmic reticulum, which operates as a selective Ca^{2+} channel in spite of its large size ($>38 \text{ \AA}$), high conductance for monovalent cations ($\approx 1 \text{ nS}$ at saturating K^{+}), permeability to solutes such as glucose, and low permeability ratio when both K^{+} and Ca^{2+} are present. This hypothesis could not yet be tested because of the lack of true PTP blockers, and of the uncertainties about the molecular nature of the PTP which prevent experiments based on genetic elimination of specific pore components.

Signaling to the PTP

PTP regulation by kinase signaling has been widely investigated. The Reperfusion Injury Salvage Kinase (RISK) group confers cardioprotection when activated during post-ischemic myocardial reperfusion or ischemic pre- and postconditioning. RISKS include the survival kinases AKT and extracellular regulated kinase 1 and 2 (ERK1/2), protein kinase C epsilon (PKC ϵ), protein kinase G (PKG), and p70s6K, and protect from

cell death by both phosphorylation of Bcl-2 family proteins and inhibition of the mitochondrial PTP, events that may well be linked. A substrate of the RISK pathway is GSK3 β which, unlike most kinases, is constitutively active in unstimulated cells where it exerts a tonic inhibitory effect on its downstream targets. GSK3 β is inactivated by serine phosphorylation induced by a variety of signaling pathways, including the one involving ERK. We have recently found that a small fraction of ERK associates to mitochondria, where it can be activated to phosphorylate (hence inactivate) GSK3 β resulting in PTP desensitization. CyP-D was associated with ERK2 and GSK3 β , and it was Ser/Thr phosphorylated, phosphorylation correlating with binding to GSK3 β and with PTP opening.

Another key kinase is hexokinase II, whose binding to mitochondria is promoted by the survival kinase AKT, which is activated by growth factors and in most tumor cells. AKT-dependent phosphorylation of mitochondrial hexokinase II inhibits Ca^{2+} -induced cytochrome *c* release, and hexokinase II association to the outer mitochondrial membrane is favored when GSK3 β is inactivated by AKT phosphorylation. Accordingly, activation of GSK3 β induces release of hexokinase II and enhances susceptibility to cell death through increased sensitivity of mitochondria to PTP induction.

Further regulatory interactions involving the PTP are emerging in the literature. A recent study demonstrated a complex mitochondrial chaperone network that involves Hsp90, its related molecule TNF receptor associated protein 1 (TRAP-1), and CyP-D. CyP-D bound to the complex was no longer available to favor PTP opening, and its displacement from the complex by selective Hsp90 antagonists reactivated the PTP with the onset of mitochondrial depolarization, release of cytochrome *c*, and massive cell death. Since the Hsp90-TRAP-1-CyPD interactions are particularly prominent in tumor cells, this strategy has been successfully used for their selective killing.

The PTP in Disease

Largely through the use of CsA, and more recently through the study of *Ppif*^{-/-} mice lacking CyP-D, key advances have been made in understanding the role of CyP-D, and to some extent of the PTP, in diseases. Here we focus on systems where an involvement of the PTP has been investigated *in vivo*.

Myocardial Ischemia-Reperfusion

The role of mitochondria in cell death extends beyond the shortage of ATP supply, and involves generation of reactive oxygen species, impairment of ion homeostasis, accumulation, and release of potentially harmful metabolites, and release of pro-apoptotic proteins such as cytochrome *c*. In the heart, mitochondrial function can paradoxically precipitate the sudden cell death that occurs when coronary flow is reestablished after prolonged ischemia (post-ischemic reperfusion). The partial recovery of mitochondrial function generates enough ATP for contraction but not for relaxation, resulting in hypercontraction and sarcolemma rupture, and a key to cardioprotection is therefore preventing mitochondrial dysfunction.

It is now well documented that the PTP represents an ideal target for cardioprotection. While ischemia does not cause PTP opening, probably because of the protective effects of intracellular acidosis, it creates the conditions for PTP opening at reperfusion because recovery of respiration in the presence of elevated cytosolic [Ca²⁺] and [Pi] provides the ideal conditions to promote PTP opening, which would be further favored by overproduction of reactive oxygen species and recovery of neutral pH. Evidence that the PTP plays a role in reperfusion injury has been obtained in isolated cardiomyocytes, perfused hearts, experimental infarction in living animals, and in a pilot study in a small number of patients. In all these cases, acute CsA administration reduced the occurrence of contractile impairment and irreversible damage. Recent results in mice where CyP-D had been genetically ablated have confirmed that lack of CyP-D confers a remarkable protection against acute infarction.

Although these issues are still controversial, PTP inhibition may also be involved in ischemic preconditioning, that is, the ability of short, repeated ischemic episodes to confer protection against a prolonged and otherwise lethal ischemia, and in ischemic postconditioning, that is, the ability to confer protection by a brief ischemic episode applied at the onset of reperfusion. In general, it appears that development of PTP blockers will be of great interest in the cardiovascular disease area.

Liver Diseases

CsA has proved to be hepatoprotective in several disease models (treatment with ethanol, with lipopolysaccharide of *E. coli* after liver sensitization with heat-inactivated *Propionibacterium* acnes or D-galactosamine, or with lipopolysaccharide alone; treatment with anti-Fas antibody, diclofenac or acetaminophen; in liver ischemia-reperfusion; in a model of α -1 antitrypsin deficiency with liver injury and mitochondrial autophagy; and in one cohort of cases of human fulminant viral hepatitis). It is difficult to assess whether the protective effects should be ascribed to PTP desensitization or rather to inhibition of cytokine production and lymphocyte activation. We systematically investigated this problem in the rat, and found that under conditions of maximal PTP desensitization by CsA *in vivo* rats were protected from the otherwise hepatotoxic effects of lipopolysaccharide plus D-galactosamine, which act through liver sensitization to the pro-apoptotic effects of tumor necrosis factor- α (TNF α).

The PTP is also involved in at least one model of hepatocarcinogenesis in rodents, that is, feeding with the arylamine 2-acetylaminofluorene (AAF), which causes onset of liver tumors within 30–50 weeks after a sequence of alterations that resembles the clinical course of chronic hepatitis, with hepatocyte damage and fibrosis gradually evolving into cirrhosis. Hepatic metabolism of AAF generates compounds that are responsible for the toxic and mutagenic effects of AAF including 2-nitrosofluorene, a redox cyler that drains electrons from the respiratory chain and causes opening of the PTP in isolated mitochondria. Very early into AAF feeding an adaptive response takes place, which desensitizes the PTP and the liver mitochondrial apoptotic pathway to TNF α *in vivo*. The adaptive response is of epigenetic nature, and represents a mitochondrial tumor-promoting event centered on the PTP that may contribute to the selection of resistant hepatocytes in the population of chemically transformed cells.

Neurological Diseases

Two convincing sets of results link the PTP to neuropathology in experimental models of neuronal injury. The first is based on the protective effects of CsA in hyperglycemia, hypoglycemia, ischemia, and trauma, in cell death following facial motoneuron axotomy in neonatal rodents, and in photoreceptor apoptosis. The second is based on mice with genetic inactivation of the *Ppif*^{-/-} gene encoding for CyP-D, which displayed a decrease of the emispheric damage that follows middle cerebral artery occlusion; a very striking resistance to axonal damage in a mouse model of multiple sclerosis; and prolonged survival after crossing into a mouse strain mimicking the familial variant of amyotrophic lateral sclerosis. This set of experiments is important because it demonstrates that the neuroprotective effects cannot be due to inhibition of calcineurin. Lack of involvement of calcineurin had also been suggested by the findings that the immunosuppressant FK506 (which inhibits calcineurin but not the PTP) failed to protect mitochondria and neurons of the dentate gyrus against hypoglycemic damage, and that *N*-methyl-Val-4-CsA, which inhibits the PTP but not calcineurin, afforded significant neuroprotection in a rat model of transient focal ischemia.

Muscle Diseases

The hypothesis that Ca^{2+} -dependent mitochondrial dysfunction plays a role in muscular dystrophies has been put forward 30 years ago. An important development in this field has been the demonstration that the PTP plays a key role in the pathogenesis of muscular dystrophy caused by collagen VI deficiency. Inherited mutations of collagen VI genes cause two muscle diseases in humans, Bethlem myopathy and Ullrich congenital muscular dystrophy. Collagen VI-deficient (*Col6a1*^{-/-}) mice display a muscle phenotype strongly resembling Bethlem myopathy, with loss of contractile strength associated with ultrastructural alterations of sarcoplasmic reticulum and mitochondria, and spontaneous apoptosis. These defects are unexpectedly due to inappropriate PTP opening because they could be normalized by treatment with CsA or with Debio 025, a cyclophilin inhibitor that does not affect calcineurin, or by crossing with *Ppif*^{-/-} mice devoid of CyP-D. Pharmacological treatment and the genetic cure rescued mitochondrial function, muscle ultrastructural defects, and dramatically decreased the number of apoptotic nuclei *in vivo* in what represents the first successful pharmacological treatment of an animal model of a genetic muscle disease.

The same mitochondrial defect was found in myoblast cultures from patients with Ullrich congenital muscular dystrophy and Bethlem myopathy, findings that paved the way for a pilot clinical trial where a dramatic short-term improvement of mitochondrial function, decreased apoptotic rates, and onset of muscle regeneration could be demonstrated in five patients. Assessing whether long-term treatment also leads to a clinical improvement will be the next step, and one that raises some hope for a therapy of this and possibly other congenital muscular dystrophies.

Glossary

Apoptosis The active process by which cells execute a series of processes leading to cell death in a way that is not harmful for the tissue and the organism. It is opposite to inflammation and necrosis, processes in which toxic products reach the neighbor cells.

Free radicals Molecules, better understood as chemical species, having an unpaired electron in their external orbitals. The feature makes the chemical species unstable and highly reactive with low specificity. However, some biologically produced free radicals, such as superoxide radicals (O_2^-) and nitric oxide (NO), are relatively stable and selective in their reactions. Other biologically produced radicals, such as hydroxyl and peroxy ($HO^\cdot$, $ROO^\cdot$) radicals,

are highly reactive and unspecific. The point near the chemical symbols indicates the unpaired electron.

Hydrogen peroxide The product of the bivalent reduction of the oxygen molecule ($HOOH$; H_2O_2); it is not a free radical, but originates $HO^\cdot$ radical upon interaction with the omnipresent Fe^{2+} .

Mitochondrial electron transfer chain A series of biological and organic molecules embedded in the inner mitochondrial membrane having chemical groups able to undergo reversible cycles of reduction/oxidation. The mitochondrial respiratory chain channels the reducing equivalents from food components and derived products to the oxygen molecule and constitutes the biochemical pathway supporting respiration.

Introduction

More than two centuries after Lavoisier's description of animal respiration as a biological oxidation, there is still a fresh and active interest in the mechanisms and the regulation of the biochemical processes that link the oxidation of food components to energy production. There is a current recognition that the regulation of biological oxidations and of energy production and expenditure underlies the whole process of life and death in cells and organisms. At the foundation of biochemistry, in the 1920s, there was a controversy on how the hydrogen atoms of organic molecules end in the H_2O molecule, with two views: hydrogen activation and oxygen activation, championed by Wieland and Warburg, respectively. The first view had H_2O_2 as an important intermediate and the second one supported the idea of H_2O as the direct product of O_2 reduction. The monumental contribution of Warburg, identifying cytochrome oxidase as the enzyme-catalyzing O_2 uptake in biological systems, ended the dispute. However, the concept of the partial reduction of O_2 in biological systems emerged again in 1946 with Michaelis' ideas of univalent electron transfer. The four univalent steps of electron transfer to the O_2 molecule would produce, according to Michaelis, hydroperoxyl radical ($HO_2^\cdot$, the protonated base of superoxide radical, O_2^-), hydrogen peroxide (H_2O_2), hydroxyl radical ($HO^\cdot$), and water (H_2O). These concepts were strengthened when Gerschman postulated in 1954 that oxygen-free radicals were the common biochemical mechanisms of oxygen and radiation toxicity. At that time, $HO^\cdot$ and $HO_2^\cdot$ were known as toxic chemical species produced in radiation chemistry and biology, but by no means it was admitted that these highly reactive free radicals could be produced in physiological conditions in animals and humans. Gerschman exposed mice to hyperbaric O_2 to increase the tissue levels of oxygen-free radicals and found synergism

between X-radiation and hyperbaric O_2 in decreasing the survival time of exposed animals.

The transcendental and landmark discovery of superoxide dismutase (SOD) by McCord and Fridovich in 1969 introduced a new dynamism to the understanding of free radical reactions in biological systems. The existence of the enzyme, first described in erythrocytes and later in bacteria and in mammalian organs, implied that O_2^- , its substrate, was a normal metabolite. In a few years, Fridovich advanced the dogma that O_2^- and H_2O_2 interact in biological systems and produce the highly toxic $HO^\cdot$, being the three chemical species responsible for oxygen toxicity and biological damage. The elegant classification of bacteria as aerobes (protected by SOD and catalase), aerotolerant anaerobes (protected by SOD but not by catalase), and anaerobes (without protection by SOD and catalase) paved the way for the extension of the 'Fridovich dogma' to mammalian biology and human pathology. Simultaneously, mitochondria were recognized in 1971–74 as an active source of H_2O_2 that diffuses to the cytosol. A series of researchers, that is, Loschen, Oshino, Flohé, Boveris, Azzi, and Richter, working under the leadership of Britton Chance at or associated with the Johnson Research Foundation (Philadelphia, USA) participated in the development of the concept. The idea collided with de Duve's 'peroxisome concept', in which H_2O_2 was produced and utilized in the intraperoxisomal space and avoided as a cellular metabolite. Shortly after Boveris and Cadenas and Azzi and coworkers simultaneously described O_2^- as the stoichiometric precursor of mitochondrial H_2O_2 , Boveris and Cadenas identified the autooxidation of ubiquinone (UQH) as an active source of O_2^- . By 1980, mitochondria were recognized as the more generalized and quantitatively more important source of O_2^- in mammalian cells and organs. Other sources of O_2^- , such as liver endoplasmic reticulum, activated neutrophils, and xanthine

oxidase, were described but their physiological importance remained restricted to specific conditions.

The existence of the family of SODs, with the Mn-SOD isoenzyme specific for the mitochondrial matrix, and the mitochondrial production of $O_2^{\cdot-}$ in all aerobic cells, were the two concepts that gave the strongest support for the participation of oxygen-free radicals in mammalian and human physiology, pathology, and aging.

The mechanistic concept that was and is currently accepted for the deleterious action of oxygen-free radicals in biological systems is called the Fenton/Haber-Weiss pathway, which involves a first step with two $O_2^{\cdot-}$ -dependent reactions: the Mn-SOD-catalyzed reaction with production of H_2O_2 and the reduction of cellular or ferritin- Fe^{3+} with production of Fe^{2+} . The second step is the reaction between H_2O_2 and Fe^{2+} that involves the homolytic scission of the peroxide bond and the generation of the highly toxic $HO^{\cdot}$ radical.

The discovery of the generation of nitric oxide (NO) in mammals as a signaling molecule with roles as intercellular messenger in the cardiovascular system, as neurotransmitter and as component of the signaling and cytotoxic mechanisms in the immunological system, along with the identification of NO as a free radical, produced a revolution in the concepts of free radical metabolism and signaling in mammals. The linear Fenton/Haber-Weiss pathway evolved to a cycles-shaped scheme for the pathways of free radical reactions in mammalian cells and organs (Figure 1).

The Mitochondrial Production of $O_2^{\cdot-}$ and H_2O_2

Mitochondria were recognized as subcellular organelles by application of supravital stainings by the end of nineteenth century, and as the site of the biochemical process of oxidative phosphorylation in the 1950s, after the availability of electron microscopy and the modern methods of cell fractionation. Mitochondrial isolation permitted the identification of complexes I–V as constitutive proteins of the inner

mitochondrial membrane and the role of the inner membrane as the coupling place for the transduction of the redox chemical energy of reduced nicotinamide adenine dinucleotide (NADH) oxidation into adenosine triphosphate (ATP) high-energy phosphate bonds. By 1955, Chance and Williams produced a complete description of the redox states of the components of the mitochondrial respiratory chain, and defined the operational concepts of mitochondrial metabolic state and of respiratory control. The latter concept elegantly describes, as the state 4 to state 3 transition, the phenomenon by which adenosine diphosphate (ADP) regulates mitochondrial electron transfer and respiration. State 4, with availability of respiratory substrate but not of ADP, is described as ‘controlled or resting respiration’, whereas state 3, with ample respiratory substrate and ADP availability, is defined as the ‘active respiration’, that is, the maximal physiological rate of ATP production and O_2 consumption. By determination of the rates of mitochondrial O_2 uptake in both state 4 and state 3, and of the O_2 uptake in tissue slices and in perfused organs, it is estimated that mammalian tissue mitochondria under basal physiological conditions are mostly (60–70%) in state 4, whereas the rest (30–40%) are in state 3, thus meaning that in the physiological setting of basal metabolism there is only a 30–40% utilization of the ATP-producing capacity.

Heart and liver mitochondria were identified as sources of H_2O_2 , in a process modulated by the mitochondrial state 4/state 3 transition; being the rate of H_2O_2 generation in state 4 markedly higher (4–6 times) than in state 3. This fact indicates that a component of the respiratory chain, markedly changing its reduction level in the state 4/state 3 transition is the H_2O_2 generator. The rates of H_2O_2 production of mitochondria isolated from mammalian organs are in the range of $0.6\text{--}0.8\text{-nmol } H_2O_2 \times \text{min}^{-1} \times \text{mg protein}^{-1}$ for state 4 and $0.05\text{--}0.15\text{-nmol } H_2O_2 \times \text{min}^{-1} \times \text{mg protein}^{-1}$ for state 3. In the case of rat heart and liver, mitochondrial H_2O_2 production accounts for about 0.5% of the tissue O_2 uptake.

The mechanistic option for mitochondrial O_2 reduction and H_2O_2 production, either one 2-electrons step to yield H_2O_2 or two 1-electron steps to yield $O_2^{\cdot-}$ as intermediate followed by dismutation, was solved by the fact that submitochondrial particles devoid of Mn-SOD show a ratio of about 2:1 in the rates of $O_2^{\cdot-}$ and H_2O_2 productions, respectively. This ratio and the intramitochondrial localization of Mn-SOD established $O_2^{\cdot-}$ as the precursor of mitochondrial H_2O_2 . The main part of mitochondrial $O_2^{\cdot-}$, about 55%, is vectorially released into the mitochondrial matrix, where it encounters Mn-SOD. Steady-state concentrations of 0.08–0.2-nM $O_2^{\cdot-}$ and 5–50-nM H_2O_2 are estimated for the mitochondrial matrix, with a content of 3–10- μM Mn-SOD. The release of $O_2^{\cdot-}$ to the mitochondrial intermembrane space, accounting for 30% of the mitochondrial $O_2^{\cdot-}$ production, was also observed in functional relationship with the Cu, Zn-SOD of this compartment. The $O_2^{\cdot-}$ released into the intermembrane space could reach the cytosol through the voltage-dependent anion channel (VDAC). Hence, mitochondria may be considered as an eventual effective source of cytosolic $O_2^{\cdot-}$, with this species contributing to the univalent redox regulation of cell signaling.

Two main $O_2^{\cdot-}$ -generating reactions have been described for the mitochondrial respiratory chain. In both cases,

Figure 1 The biochemical free radical chain reactions encompassed by the redox transitions of $O_2^{\cdot-}$ (red), NO (blue), and ubiquinone (green). $O_2^{\cdot-}$, superoxide anion; H_2O_2 , hydrogen peroxide; $HO^{\cdot}$, hydroxyl radical; NO , nitric oxide; $ONOO^{\cdot}$, peroxynitrite; UQH_2 , ubiquinol; $UQH^{\cdot}$, ubisemiquinone; UQ , ubiquinone.

Figure 2 Sites of O_2^- production in the mitochondrial respiratory chain. UQH₂, ubiquinol; UQ, ubiquinone; and UQH[•], ubisemiquinone. The percentages close to O_2^- indicate the relative contribution of each chemical pathway to total mitochondrial O_2^- production.

the intermediate are semiquinones of redox pairs of the respiratory chain: the pair ubiquinol/ubiquinone and the pair reduced flavin mononucleotide (FMNH₂)/FMN component of NADH dehydrogenase. The two semiquinones, UQH[•] and FMNH[•], respectively, are collisionally and nonenzymatically autooxidized by molecular O_2 yielding O_2^- as product. In the UQH[•] autooxidation, the chemical process is called the Boveris–Cadenas reaction ([reaction \[1\]](#)), with a second-order reaction constant of $8 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$, and with the reaction considered the main mitochondrial O_2^- -producing pathway and a pacemaker of mitochondrial turnover and of the aging process.

Figure 2 illustrates the mitochondrial reactions that produce O_2^- as well as their vectorial release to the cytosol and to the intermembrane space. Autooxidation of other components of the mitochondrial respiratory chain are thermodynamically spontaneous, but these reactions are not kinetically fast enough to be important on a quantitative consideration.

The spontaneous surface chemiluminescence of *in situ* organs supported the idea of mitochondria as the main physiological source of oxidizing free radicals. The assay is based in the production of the chemiluminescent species singlet oxygen (1O_2), a downstream byproduct of lipid peroxidation generated in the reaction of $ROO^{\bullet}$ radical recombination ([Figure 1](#)). *In situ* liver and brain chemiluminescence increased under conditions, such as hyperbaric O_2 , ischemia–reperfusion, and pharmacological treatments, following the quantitative effect of these conditions on mitochondrial O_2^- generation.

The Mitochondrial Production of 'NO

The extraordinary research activity on biological 'NO production at the beginning of the 1990s identified three different

nitric oxide synthases (NOSs): neuronal NOS (NOS-I or nNOS), inducible or macrophage NOS (NOS-II or iNOS), and endothelial NOS (NOS-III or eNOS). Immunocytochemical assays with antibodies against eNOS gave evidence of an NOS located in mitochondria, which was named mtNOS and advanced as a regulator of mitochondrial and cellular respiration. The determination of mtNOS enzymatic activity with 'NO as product was elusive for a few years, until two independent groups, Ghafourifar and Richter in Zurich, and Giulivi, Poderoso, and Boveris in Los Angeles and Buenos Aires, succeeded in 1997–98 in measuring a 'NO production by rat liver mitochondria and mitochondrial fragments. The original observations in liver mitochondria were later extended to mitochondria from brain, heart, thymus, kidney, and skeletal muscle, thus dissipating the skepticism on mtNOS that stemmed from the supposition of contamination during cell fractionation. Mitochondrial 'NO production is carried out by mtNOS, a classic NOS, that requires NADPH ($K_M = 12\text{--}20 \mu\text{M}$), arginine ($K_M = 5\text{--}50 \mu\text{M}$), O_2 ($K_M = 35\text{--}40 \mu\text{M}$), and Ca^{2+} for enzyme activity. Calmodulin, tetrahydrobiopterine, and thiols increase the enzymatic activity. Intramitochondrial concentrations of NADPH, arginine, O_2 , and Ca^{2+} are in excess or in the range needed for enzymatic activity. The methodology currently used to measure mtNOS activity determines 'NO production rates of $0.80\text{--}1.60\text{-nmol 'NO}_x \text{ min}^{-1} \times \text{mg protein}^{-1}$ in mitochondria and submitochondrial preparations.

In a pivotal contribution in 2002, Giulivi and coworkers sequenced the 1429 amino acids of rat liver mtNOS and found it identical to nNOS splice variant α , mirystoylated and phosphorylated in posttranslational processes. Transcripts corresponding to nNOS- α were found in liver, brain, heart, kidney, skeletal muscle, lung, testis, and spleen. Hence, it is now clear that mtNOS is a constitutive protein of the inner mitochondrial membrane with the reaction center facing the matrix side and with its substrates present in the mitochondrial matrix. Interestingly, a series of physiological situations were

reported to regulate the expression and activity of mtNOS that was reported upregulated by acute and chronic hypoxia, by insulin, and by cold exposure, and downregulated by thyroxine and angiotensin II. Pharmacological administration of enalapril increased heart and kidney mtNOS activity and treatments with haloperidol and chlorpromazine decreased brain mtNOS activity.

Intramitochondrial steady-state concentrations of $\cdot\text{NO}$ are calculated as 200–370 nM (200 nM in state 3 and 370 nM in state 4) and a release of 29 nM $\cdot\text{NO}$ was electrochemically measured after supplementation of a single mitochondrion with Ca^{2+} . In the tissues under physiological conditions at 20- μM O_2 , the $[\text{O}_2]/[\cdot\text{NO}]$ ratio is 100–55, which would inhibit cytochrome oxidase by 30–45 %. In the mitochondrial matrix, $\cdot\text{NO}$ and $\text{O}_2^{\cdot-}$ metabolism are linked by the very fast reaction between the two free radicals to produce ONOO^- . This oxidative utilization of $\cdot\text{NO}$ is the main (60–70%) pathway of $\cdot\text{NO}$ catabolism, but at the same time it is only a minor part (15%) of intramitochondrial $\text{O}_2^{\cdot-}$ utilization. The reductive utilization of $\cdot\text{NO}$ by ubiquinol and cytochrome oxidase provides a minor (20%) pathway of $\cdot\text{NO}$ catabolism. The cellular conditions in which $\cdot\text{NO}$ diffuses from mitochondria to cytosol, as well as the conditions in which $\cdot\text{NO}$ diffuses from cytosol to mitochondria are unsolved questions for the complex process of intracellular signaling. The available data support a bipolar distribution of NOS in the cells, with an isoenzyme in mitochondria (mtNOS) and the other in the cytosol (endoplasmic reticulum or synaptic vesicles). **Figure 3** shows a view of the integrated mitochondrial metabolism of $\text{O}_2^{\cdot-}$ and $\cdot\text{NO}$.

The main effect of $\cdot\text{NO}$ on mitochondrial electron transfer was reported in 1994 by two British research groups, Brown and Cooper and Cleeter et al., that described the inhibition of brain and muscle cytochrome oxidase (complex IV) activity by

low- $\cdot\text{NO}$ concentrations in a reversible and O_2 -competitive biochemical process. The observation was rapidly confirmed by other groups using $\cdot\text{NO}$ donors and pure $\cdot\text{NO}$ in liver, heart, and brown fat mitochondria. Nitric oxide at 0.1–0.2 μM decreases cytochrome oxidase activity and mitochondrial respiration to one-half. The inhibition is reversible by dilution, hemoglobin supplementation, or exposure to $\text{O}_2^{\cdot-}$. The $\text{O}_2^{\cdot-}$ competitive inhibition of cytochrome oxidase renders the effect more marked at low O_2 concentrations. A mathematical model by Antunes et al. explains the main features of the $\cdot\text{NO}$ effects on mitochondrial respiration: dependence with $\cdot\text{NO}$ concentration, dependence with O_2 concentrations (as the $\cdot\text{NO}/\text{O}_2$ ratio), and a more marked effect of $\cdot\text{NO}$ in state 3 than in state 4. A second sensitive point in the mitochondrial respiratory chain is complex III (ubiquinol–cytochrome *c* reductase); half inhibition of electron transfer between cytochromes *b* and *c* occurs at 0.2–0.4- μM $\cdot\text{NO}$ with the interesting property of enhancing the production of $\text{O}_2^{\cdot-}$ and H_2O_2 in submitochondrial particles and in mitochondria. A third sensitive respiratory component is NADH-dehydrogenase (complex I) and in this case, ONOO^- appears as the effective inhibitory agent in an irreversible process. Complex I inactivation is of great interest in pathological conditions as it has been reported in a series of neurodegenerative diseases, originally in Parkinson's disease, and referred as 'complex I syndrome'.

Figure 4 illustrates the direct and indirect effects of $\cdot\text{NO}$, in the latter case through ONOO^- formation, on the mitochondrial respiratory chain. The reversible effects of $\cdot\text{NO}$ on cytochrome oxidase and complex III are two aspects of the regulation of mitochondrial respiration by $\cdot\text{NO}$: the direct inhibition of cytochrome oxidase, and the enhancement of $\text{O}_2^{\cdot-}$ production to remove the respiratory inhibition, as it may become a physiological need in the case of high steady-state concentrations of $\cdot\text{NO}$, such as in inflammation and in

Figure 3 Metabolism of $\text{O}_2^{\cdot-}$ and $\cdot\text{NO}$ in the mitochondrial matrix. The numbers below the symbols indicate physiological steady-state concentrations. The arrows reaching outside the mitochondrion indicate diffusion of H_2O_2 and $\cdot\text{NO}$ to the cytosol in the indicated conditions.

Figure 4 Sites of action of $\cdot\text{NO}$ and ONOO^- on the mitochondrial respiratory chain. Reversible and irreversible indicate the types of inhibition that are understood as regulatory or toxic processes, respectively. The indicated steady-state concentrations were determined or estimated to reduce enzymatic activities to one half, at a concentration of 100–150 μM O_2 .

ischemia–reperfusion. The irreversible effects of ONOO^- on complexes I and III are related to situations in which sustained high levels of ONOO^- lead to mitochondrial dysfunction and apoptosis.

Concerning the important question of whether or not mtNOS enzymatic activity regulates mitochondrial functions under physiological conditions, several reports described the modulation of mitochondrial O_2 uptake and H_2O_2 production by the activity of mtNOS in isolated mitochondria. The current view is that mtNOS does regulate mitochondrial respiration. Hence, mtNOS, cytochrome oxidase, and $\text{F}_1\text{-ATPase}$ are the three regulatory proteins of cellular O_2 uptake and energy production. The biochemical activity of mtNOS (expressed as $\text{nmol NO} \times \text{min}^{-1} \times \text{mg protein}^{-1}$) is usually measured as the mitochondrial $\cdot\text{NO}$ production (sensitive to a competitive inhibitor of NOS, such as NG-monomethyl-arginine (NMMA) or nitroarginine (NNA)). The regulatory activity of mtNOS, named the functional mtNOS activity, is best expressed by the difference in the rates of O_2 uptake or H_2O_2 production (in $\text{nmol of O}_2 \text{ or H}_2\text{O}_2 \times \text{min}^{-1} \times \text{mg protein}^{-1}$) between mitochondria supplemented with arginine and SOD, condition that provides the highest $\cdot\text{NO}$ steady state, and mitochondria in the presence of HbO_2 and of a NOS competitive inhibitor (NMMA or NNA), that gives the lowest $\cdot\text{NO}$ steady-state level. The regulatory capacity of $\cdot\text{NO}$ is estimated as the ratio of the rates of regulated O_2 uptake or H_2O_2 production over the rate of $\cdot\text{NO}$ production; the ratio is ~ 70 for O_2 uptake and ~ 0.4 for H_2O_2 production. The activity of mtNOS, that is, the steady-state level of $\cdot\text{NO}$ in isolated mitochondria and cells, markedly increases the $[\text{O}_2]_{0.5}$ of mitochondrial O_2 uptake; for mitochondria, the values changed from 1.1- μM O_2 in the case of inactive mtNOS to 2.2- μM O_2 in the case of an active mtNOS. However, it remains to be established to what extent these effects, observed with isolated mitochondria occur under physiological

conditions in myoglobin-containing tissues and in blood-perfused organs, due to the high affinity of the two mentioned hemoproteins for $\cdot\text{NO}$.

The Physiological Role of the Mitochondrial Production of $\text{O}_2^{\cdot-}$, H_2O_2 , and $\cdot\text{NO}$

The early recognition that $\text{O}_2^{\cdot-}$ and H_2O_2 are both able to initiate reactions harmful to cell and tissues is now complemented by the concept that $\text{O}_2^{\cdot-}$, H_2O_2 , and $\cdot\text{NO}$ are carefully regulated metabolites capable of signaling to the regulatory receptors of the biochemical and genetic systems of the cell. Nitric oxide was initially recognized as an intercellular messenger and later as an intracellular regulator. At present, the three chemical species, $\text{O}_2^{\cdot-}$, H_2O_2 , and $\cdot\text{NO}$, are considered to participate in integrated processes of intracellular regulation and in intercellular signaling, communication, and cytotoxicity. Although $\text{O}_2^{\cdot-}$ is considered a metabolite confined to the intramitochondrial space, with minor release to cytosol through VDAC, both H_2O_2 and $\cdot\text{NO}$ are permeable through the double mitochondrial membrane and plasma membrane and are likely regulators of cytosolic and neighbor cell functions. Hydrogen peroxide and $\cdot\text{NO}$ share the chemical property of being uncharged and the biological property of being highly diffusible through biological membranes. At variance, $\text{O}_2^{\cdot-}$ and ONOO^- are charged and nondiffusible molecules. Consequently, the first two species are suitable for cellular and intercellular signaling and the two latter for regulation and cytotoxicity in confined spaces. The regulation of gene expression and intercellular communication is just starting to be understood as a vital mechanism in health and disease.

The fine regulation by H_2O_2 of cell function was advanced by Antunes and Cadenas in 2001 when they treated Jurkat

T-cells with controlled H_2O_2 concentrations provided by the glucose–glucose oxidase system. Steady-state concentrations below $0.7\ \mu\text{M}$, H_2O_2 place cells in a proliferative state, whereas at $1.0\text{--}3.0\ \mu\text{M}$, H_2O_2 cells develop programmed cell death, and at levels higher than $3.0\ \mu\text{M}$ H_2O_2 cells undergo necrosis.

There is evidence that H_2O_2 and NO are able to upregulate mitogen-activated protein kinases (MAPKs), the widespread components of intracellular phosphorylation and dephosphorylation signaling cascades involved in cell survival, proliferation, differentiation, and death. The interactions are complex and involve intracellular glutathione and ONOO^- . Both, H_2O_2 and NO diffusing from mitochondria to the cytosol are considered a pleiotropic signal involved in the regulation of c-Jun-N-terminal kinase (JNK)-dependent signaling, with H_2O_2 upregulating JNK1 and NO inactivating JNK1, likely by S-nitrosylation). The concept of narrow ranges of intracellular messenger molecules for different or opposite biological actions, as observed for H_2O_2 levels in the proliferation/apoptosis transition, is now applied to effector systems with two likely regulators, H_2O_2 and NO , and with the consequence of different responses for the integration of the two signals in one response (Figure 5).

It has been understood for the last 40 years that excess generation of O_2^- and H_2O_2 leads to oxidative stress and harmful biological situations. Nitric oxide has been added to these two species in the last two decades. The classical concept of oxidative stress, as brought forward by Sies, implies an imbalance between oxidants and antioxidants, in favor of the former. The situation is understood as reversible, especially by supplementation with antioxidants, and also as leading, sooner or later, to biological dysfunction. The concept is applicable to subcellular organelles, cells, organs, systems, and whole organisms. From a biochemical perspective, oxidative stress is determined by an increased steady-state level of at least one of the following chemical species, O_2^- , H_2O_2 , NO ,

ONOO^- , $\text{HO}^\cdot$, $\text{ROO}^\cdot$, and $^1\text{O}_2$, leading, according to the mass action law, to increased production and levels of the other oxidizing species downstream of the free radical chain reaction pathway (Figure 1) and to biochemical damage.

Oxidative Stress and Dysfunctional Mitochondria: Mitochondria as Targets of Free Radicals

In the last few years, the concept of dysfunctional mitochondria was applied to mitochondria isolated from tissues showing oxidative stress, biological damage, physiological dysfunction or pathological conditions. Mitochondria are considered dysfunctional by comparison of their functions and properties with normal control mitochondria. The classic mitochondrial properties, that reflect the energy-producing physiological function, are: the state 3 rate of O_2 uptake, the respiratory control, the membrane potential, and the ADP:O ratio. These parameters, when decreased, support the consideration of dysfunctional mitochondria. In addition, dysfunctional mitochondria frequently show increased rates of O_2^- and H_2O_2 production, a condition that contributes to the perpetuation of the dysfunctional condition.

Mitochondrial dysfunction has been observed in ischemia-reperfusion, endotoxic and septic shock, a series of pathological situations, aging, and neurodegenerative diseases. The reported characteristics are: decreases in the rates of state 3 respiration and ATP synthesis, in mitochondrial membrane potential, and in respiratory control, and increases in state 4 respiration, in mitochondrial size and fragility, and in the content of free-radical-mediated oxidation products of proteins, phospholipids, and DNA. The reported decreases in the rates of state 3 respiration and of mitochondrial electron transfer in the isolated respiratory complexes are in the range of 30–40%; it seems that more damaged mitochondria are not compatible with living cells.

The continuous production of oxidizing chemical species is the concept that explains the molecular mechanisms involved in the evolution from normal to dysfunctional mitochondria. The free radical O_2^- is continuously produced in the autooxidation of $\text{UQH}^\cdot$ and $\text{FMNH}^\cdot$ and mainly dismutates to H_2O_2 ; also, the free radical NO is continuously produced by mtNOS as regulator of respiration. The species ONOO^- is produced by the collision of O_2^- and NO in the fastest reaction known in biological systems ($k = 1.9 \times 10^{10}\ \text{M}^{-1}\ \text{s}^{-1}$), except for the neutralization reaction of H^+ and $\text{HO}^\cdot$ ($k = 14 \times 10^{10}\ \text{M}^{-1}\ \text{s}^{-1}$). Peroxynitrite is a nitrating and oxidizing species; when produced in excess, as in ischemia-reperfusion and inflammation, leads to tyrosine nitration of mitochondrial proteins. Intramitochondrial levels of 3–5-nM ONOO^- have been estimated for physiological conditions, and levels above 20–30 nM are considered cytotoxic. The free radicals $\text{HO}^\cdot$ and $\text{ROO}^\cdot$ are the products of the Fenton/Haber-Weiss reaction and of the process of lipid peroxidation. The oxidation products of phospholipids and proteins (thiobarbituric acid reactive substance (TBARS), 4-HO-nonenal and protein carbonyls) are constantly detected in dysfunctional mitochondria. Dysfunctional mitochondria appears almost equally driven by excessive NO and ONOO^- production and by excessive lipid peroxidation.

Selective inhibition of NADH-dehydrogenase (complex I) activity associated to increased lipid peroxidation and nitration

Figure 5 Mitochondrial production of oxygen- and nitrogen-centered radicals and cell signaling. The scheme shows the sites of action of NO in the respiratory chain, the ensuing production of O_2^- and of H_2O_2 , the release of these reactive species from the mitochondrion (controlled by VDAC in the case of O_2^-) and the effect on JNK signaling.

has been reported in mitochondria and submitochondrial preparations from dysfunctional organs, especially from experimental animals and human neurodegenerative diseases. This selective mitochondrial defect is understood as secondary to a sustained oxidative stress and was reported in aged humans and in patients with neurodegenerative disorders, among them Parkinson's and Alzheimer's diseases. The near-target production of $O_2^{\cdot-}$ (by NADH-dehydrogenase) and of $ONOO^-$ are considered determinant in the selective impairment of complex I in neurodegenerative diseases. The concept of complex I syndrome implies a decreased rate of state 3 mitochondrial respiration with NAD-linked substrates, a decreased complex I activity, and an increased content of proteins and phospholipids oxidation products. These characteristics describe the findings in animal models and in human patients of Parkinson's and Alzheimer's diseases and of dementia with Lewy bodies, among other neurodegenerative diseases.

The continuous mitochondrial production of free radicals and oxidizing species makes mitochondria the quantitatively most important source of these harmful species in the cell, and at the same time, the sensitivity of mitochondrial functions to increased levels of the oxidizing free radicals and related chemical species renders mitochondria the most sensitive cellular target for the deleterious action of free radicals. The rapid mitochondrial turnover ($t_{1/2}$ of 7–10 days in liver and of 30–40 days in heart and brain) clearly faster than cell turnover (40–50 days in liver and almost infinite in brain neurons) illustrates the double role of mitochondria as source and target of biologically harmful free radicals.

Mitochondrion-Dependent Apoptosis

The role of mitochondria in apoptosis is now well established; a specific mitochondrion-dependent pathway of cell death is differentiated from the death-receptor-mediated apoptosis. Mitochondrion-dependent apoptosis entails oxidative stress and is modulated by MAPK signaling through JNK activation associated with Bcl-2 downregulation, cytochrome *c* release, and the downstream activation of caspases. A very early activation of mtNOS has been reported in thymocyte-induced apoptosis. Thapsigargin supplementation of isolated thymocytes sequentially increases cytosolic Ca^{2+} and the activities of mtNOS and of the NOS of endoplasmic reticulum. A crosstalk between mitochondria and endoplasmic reticulum, in which Ca^{2+} and 1NO are the signals, is established in the initial phase of thymocyte apoptosis followed by the well-established mitochondrial changes that are characteristic of mitochondrion-mediated apoptosis: fall in mitochondrial membrane potential, mitochondrial dysfunction, opening of the membrane transition pores (MTPs), and cytochrome *c* release.

The central role of mitochondria in the cell death program is exerted during the first and reversible phase of early apoptosis through the markedly increased release of H_2O_2 and 1NO to either activate cytosolic JNK which attached to mitochondria catalyzes phosphorylation of Bcl-2 and Bcl- x_L and other not yet identified mitochondrial proteins. The JNK-mediated phosphorylations initiate the steps of the second and irreversible phase of apoptosis by opening the inner MTP and by releasing

Ca^{2+} and $O_2^{\cdot-}$ to the intermembrane space, followed by the opening of the outer MTP and release of cytochrome *c* to the cytosol. The next steps in the execution of the cell death program, such as apoptosome assembly and caspase activation, are independent of mitochondrial intervention.

The Mitochondrial Hypothesis of Aging – Aging and Neurodegenerative Diseases

In the last few years, a strong current of opinion has linked the processes of mitochondrial production of $O_2^{\cdot-}$ and H_2O_2 , with continuous oxygen toxicity, aging, life span, and neurodegenerative diseases. In the mitochondrial hypothesis of aging, mitochondria are considered as a biological clock for mitochondrial turnover, cell aging, and apoptosis. The free radical theory of aging was proposed by Harman in 1956, who after observing that supplementation of animal food with organic antioxidants increased the median life span in rats and mice, considered that aging is caused by the cumulative and random effects of free radicals that were cancelled by antioxidants. The antioxidant effect is now understood in terms of the continuous mitochondrial production of $O_2^{\cdot-}$ and 1NO as primary free radicals, with a whole series of derived and oxidizing reactive species, such as H_2O_2 , $ONOO^-$, $HO^{\cdot}$, $ROO^{\cdot}$, and 1O_2 . This continuous production supports the notion of mitochondria as pacemakers of cell and organ aging. As mentioned above, increased intramitochondrial steady-state concentrations of reactive oxygen and nitrogen species have been associated to the appearance of dysfunctional mitochondria in situations of acute oxidative stress, such as ischemia–reperfusion, and endotoxic or septic shocks and of chronic oxidative stress such as aging and neurodegenerative diseases. Increased levels of oxidative stress markers, such as 8-hydroxy-deoxyguanosine, protein carbonyls, hydroperoxides, and TBARS, have been consistently reported upon aging. Dysfunctional mitochondria with decreased state 3 respiration, membrane potential and respiratory control, and with increased size have been reported upon aging. Interestingly, some of the altered parameters were partially or near totally normalized by treatment with antioxidants, such as high doses of vitamin E and plant extracts.

It is noteworthy that some mitochondrial macromolecules appear selectively damaged upon aging. In this way, mitochondria are the pacemaker of aging, both as the main continuous source and as the main target of oxidizing free radicals. Ames and coworkers pioneered the field with the observation of increased mitochondrial DNA (mtDNA) damage, expressed as 8-hydroxy-deoxyguanosine in tissues and in urine, in old animals as compared with young ones. Other mitochondrial macromolecules, such as mitochondrial RNA (mtRNA) and the regulatory factor Bcl-2, have been reported damaged upon aging. Mitochondrial enzymes that are crucial for electron transfer and energy production, such as complexes I and IV, adenine nucleotide translocase, and carnitine-acyl transferase, are selectively decreased upon aging. Two hypothesis or lines of thought, link these observations. One of them considers that a decreased mitochondrial biogenesis is the driving phenomenon. The normal process of mitochondrial biogenesis, regulated by cellular 1NO , is slowed down by a lower level of 1NO steady-state concentration. Aged mitochondria

accumulate oxidation products and evolve to dysfunctional mitochondria, signaling for apoptosis. It is considered that mitochondria in simultaneous processes “respire (take up O_2 and release CO_2), generate $O_2^{\cdot -}$ and H_2O_2 , and undergo phospholipid peroxidation and enzyme inactivation.” The second hypothesis is that damaged mtDNA and mtRNA will produce, through defective mitochondrial protein synthesis, faulty polypeptides that would contribute along with protein carbonyls, hydroperoxides, and TBARS, to suboptimal enzyme function and the appearance of dysfunctional mitochondria. These dysfunctional mitochondria signal for lysosomal digestion, autophagy, or apoptosis. In all cases, the decrease in energy availability and in tissue-active cells, consequence of the decreased amount of functional mitochondria due to enhanced cell death, leads to the reduction of tissue physiological functions that is characteristic of aging.

Glossary

Extracellular signal-regulated protein kinase (ERK) One class of mitogen-activated protein kinases (MAPKs).

Guanosine triphosphatases (GTPases) Molecular switches that control cellular responses by exchanging guanosine diphosphate (GDP) (inactive form) for guanosine triphosphate (GTP) (active form) in response to a variety of stimuli. In the GTP-bound form they interact with effector molecules. Subsequently, they hydrolyze GTP to GDP, thereby returning to their inactive state.

Mitogen-activated protein kinases (MAPKs) A group of serine/threonine protein kinases that play an essential role

in signal transduction in response to changes in the cellular environment.

Protein kinases Phosphotransferases that catalyze the transfer of a phosphate group from adenosine triphosphate (ATP), or in some cases from GTP, to a protein substrate. Most protein kinases phosphorylate serine or threonine residues (serine–threonine protein kinases) or tyrosine residues (protein tyrosine kinases).

Ras A small GTPase that controls the activation of the ERK kinase cascade, as well as other downstream targets.

Mitogen-activated protein kinases (MAPKs) are a group of protein kinases that play an essential role in signal transduction by modulating gene transcription in the nucleus in response to changes in the cellular environment. MAPKs also play a key role in intracellular communication, and their activating pathways have been conserved throughout evolution, from plants, fungi, nematodes, insects, to mammals. In humans, there are at least 11 members of the MAPK superfamily, which can be divided into six groups: the extracellular signal-regulated protein kinases (ERK1 and ERK2); c-Jun N-terminal kinases (JNK1, JNK2, and JNK3); p38s (p38 α , p38 β , p38 γ , and p38 δ); ERK5 (ERK5); ERK3s (ERK3, p97 MAPK, and ERK4); and ERK7s (ERK7 and ERK8). Each group of MAPKs can be stimulated by a separate signal transduction pathway in response to different extracellular stimuli. In turn, MAPKs exhibit distinct substrate specificities. Thus, individual extracellular stimuli can lead to the differential activation of each MAPK and the consequent phosphorylation of a distinct set of MAPK substrates. Whereas components of some of these biochemical routes are now well established, others are still poorly understood. The specificity of the molecular mechanisms by which each MAPK can be activated ensures that cells mount an appropriate response to extracellular stimulation, as the resulting pattern of gene expression will depend on the integration of the combinatorial signals provided by the temporal activation of each of these groups of MAPKs.

ERK Family

ERK1 and ERK2

The extracellular signal-regulated protein kinase (ERK) group of MAPK includes ERK1 and ERK2. In certain cells their activation contributes to normal and aberrant growth, including malignant transformation, while in other cells this pathway can promote cell survival or initiate differentiation processes in others. The enzymatic activity of ERK1 and ERK2 is enhanced

by dual phosphorylation on Thr and Tyr residues within a short sequence that forms the activation loop, located close to the kinase active site, by a group of dual-specificity protein kinases (MAPK kinases; MAPKKs), represented by MEK1 and MEK2. Each MAPK family exhibits a distinct phosphor-acceptor motif in their activation loop (**Figure 1**), which provides specificity for the MAPKK–MAPK interactions. This phosphorylation leads to conformational changes in ERKs, thereby promoting their activation and nuclear localization. Subsequently, ERK activity is terminated by dephosphorylation on either Thr or Tyr by a Ser/Thr or Tyr phosphatase. This dephosphorylation can be mediated also by a dual specificity MAPK phosphatase. Similarly, the mammalian MAPKKs, such as MEK1 and MEK2, are activated by phosphorylation mediated by MAPK kinase kinases (MAPKKKs), which includes the Ras effector, Raf. Thus, the Raf group of MAPKKK that includes A-Raf, B-Raf, and c-Raf-1 plays an important role in the coupling of ERK MAPK activation to the Ras signaling pathway (see **Figure 2**).

The discovery of the Ras–Raf–MEK–ERK signaling route represented a breakthrough in cancer biology, and emerged as the product of the conversion of a large number of research efforts in a variety of otherwise poorly connected fields. Indeed, a large body of information was derived from genetic analyses of model organisms including *Drosophila*, *Saccharomyces cerevisiae*, and *Caenorhabditis elegans*, in addition to biochemical and biological studies in mammalian cells. They, collectively, led to the identification of Ras as a key downstream component of the pathway initiated by polypeptide growth factor receptors, and to the realization that this small GTPase acts subsequently as a master switch initiating the activity of a cascade of cytoplasmic kinases that culminate with the activation of the ERK1 and ERK2. ERKs, in turn, direct the activities of many nuclear transcription factors, thus regulating gene expression. These findings provided a better understanding of the molecular basis for the transduction of proliferative signals, as well as the first clue as to how the aberrant function of Ras proteins may contribute to the malignant conversion of cancer cells.

The GenBank accession numbers are human ERK1 (X60188), human ERK2 (M84489), human ERK3 (S23429), human p97 (X80692), human ERK4 (P31152), human ERK5 (U25278), human BMK (U29725), Rat ERK7 (AF078798), human ERK8 (AY065978), human JNK1 (U34822), human JNK2 (U34821), human JNK3 (U34820), human Mxi2 (U19775), CSBP1 (S52419), CSBP2 (S52420), human p38 β (U53442), and human p38 γ (U66243).

Figure 2 MAPK signaling cascades. Schematic representation of generic (left), mitogen-activated (center), and stress-activated (right) signaling cascades. Separate signal transduction pathways initiated by different extracellular stimuli activate each group of MAPKs that, in turn, exhibit distinct substrate specificities.

c-Jun N-Terminal Kinases (JNK1, JNK2, and JNK3)

JNK was initially discovered by its ability to phosphorylate the N-terminal transactivating domain of the transcription factor c-Jun. As its activity was stimulated primarily by cellular stress

rather than by mitogens, contrary to ERKs, it was also termed 'stress-activated protein kinase (SAPK)'. It is now known that there are three members of the JNK family, JNK1–3, and that they play numerous biological roles in response to a large variety of cell surface receptors as well as physical and chemical

stresses. Whereas the JNK1 and JNK2 genes and their alternatively spliced variants are expressed ubiquitously, generating a total of eight JNK isoforms, the JNK3 gene has a more restricted expression pattern, being its two alternative spliced transcripts expressed the highest in brain and testis. Studies of mammalian cells demonstrated that JNK is required for neuroexcitatory stress-induced neuronal apoptosis, as well as for certain inflammatory responses and for the survival and malignant transformation of specific cell types (e.g., B cells).

Following the distinct pattern of activation of ERK and JNK by cellular receptors, an unexpected discovery was that whereas Ras regulates ERKs, two members of the Rho family of GTPases, Rac1 and Cdc42, initiate an independent kinase cascade regulating JNK activity. These findings provided direct evidence of a role for Rho GTPases in transcriptional regulation, thus expanding previous efforts addressing the function of these Rho-related proteins, which were primarily focused on the molecular dissection of the mechanism(s) involved in their ability to control the dynamic assembly and remodeling of actin-containing cytostructures. Components of this pathway include several MAPKKKs: MEKK1, MEKK2, MEKK3, and MEKK4, apoptosis-stimulated kinase 1 (ASK1), mixed-lineage kinase 3 (MLK3), tumor progression locus 2, also known as Cot (TPL2), TGF- β -activated kinase (TAK), MAPK upstream kinase (MUK), germinal center kinase (GCK), and PAK, which can all contribute to activation of JNKs, apparently through two MAPKKs, MKK4 (also called Sek or JNKK1), and MKK7. Substrates for JNK include transcription factors of the c-Jun family, as well as other transcription factors, including Elk-1 and Elk-2, serum response factor accessory protein-1 (Sap-1), nuclear factor of activated T cells 4 (NFAT4), and activating transcription factor 2 (ATF2).

p38s (p38 α , p38 β , p38 γ , and p38 δ)

The family of p38 kinases has expanded over the past few years, including now four members known as p38 α (or CSBP-1), p38 β , p38 γ (also known as SAPK3 or ERK6), and p38 δ (or SAPK4), and in some cases their corresponding splice variants. These MAPKs share a Thr–Gly–Tyr phosphorylation motif in their activation loop, and are stimulated by receptors and environmental stresses similar to those provoking the activation of JNKs. These enzymes are particularly sensitive to their stimulation by exposure of cells to endotoxins, including bacterial lipopolysaccharides. Evidence of their role in transducing stress signals can be found as far phylogenetically as in yeast, where genetic analysis indicates that the Hog1p MAPK, the yeast homolog of p38, is required for the response to osmotic stress that involves the enhanced expressions of genes participating in the biosynthetic pathway of the osmotic stabilizer glycerol.

As for the ERKs, p38s are activated by dual phosphorylation on Thr and Tyr residues by MKK3 and MKK6, the latter being a general stimulator for p38s and the former exhibiting certain preference for p38 α . The immediate upstream activators for these kinases are not yet well defined and include the potential p38 MAPKKKs known as ASK1 and TAK1. The specific transcription factors that can be regulated by p38s include cAMP-responsive element-binding protein (CREB), activating transcription factor 1 (ATF1), ATF2, Max, C/EBP homologous

protein (CHOP), and MEF2C. In addition, these MAPKs can also trigger the activation of other serine–threonine kinases such as Mnk1 (MAPK-interacting kinase 1) and Mnk2 and MAPK-activated protein kinases (MAPKAPKs).

ERK5

ERK5, also known as big mitogen-activated protein kinase (BMK1), is distantly related to ERK1 and ERK2. Although it contains a Thr–Glu–Tyr motif in its activation loop, similar to that of ERK1 and ERK2, ERK5 is larger than any other known MAPK (~80 kDa) and is selectively activated by MEK5 but not by MEK1 or MEK2. This kinase can be stimulated by oxidative stress, and can play a role in early gene expression triggered by epidermal growth factor and serum by the direct phosphorylation of the transcription factors MEF2C or c-Myc, thereby participating in cell proliferation and progression through the cell cycle. Although information on this MAPK is still limited, evidence supporting its role in cell growth is also provided by its ability to cooperate with the activated Raf or MEK, which act on ERK1 and ERK2, to promote neoplastic transformation. The physiological function of ERK5 is nevertheless still unclear, and further studies are required to establish the biological role of this MAPK signaling pathway.

Others (ERK3, ERK4, ERK7, and ERK8)

Novel members of the MAPK family, ERK 7 (61 kDa) and ERK8, also contain a Thr–Glu–Tyr activation motif. ERK8 was cloned using the rat ERK7 complementary DNA (cDNA) to screen a human multiple tissue cDNA library and share an overall amino acid sequence identity of 69%. In contrast to rat ERK7, ERK8 does not display significant constitutive kinase activity, does not phosphorylate c-Fos, and is activated in response to stimulation by Src or serum. ERK3 contains a Ser–Glu–Gly activation motif, with gly in place of tyr. The ERK3 subfamily of MAPKs is composed of two functional genes, MAPK6 (p97 MAPK) and MAPK4 (ERK4), and several pseudogenes. Upstream activators of ERK3 are still poorly defined, and this kinase is not present in yeast or *C. elegans*. None of the currently known MEK family members is able to phosphorylate and activate ERK3 and no physiological substrates of ERK3 have been found. ERK3 is localized constitutively to the nucleus without conventional nuclear localization sequences.

Specificity and Fidelity in Nuclear Signal Transmission by MAPK Signaling Pathways

Protein kinases typically interact with their substrates by recognizing primary sequence determinants that surround the phosphorylation site(s). In the case of MAPK, the minimum general primary sequence required to be a substrate for protein phosphorylation is the presence of a Ser or Thr residue followed by Pro. Additionally, most MAPKs also appear to interact with their substrates by binding to a second site. This docking interaction is required for substrate phosphorylation by MAPK *in vitro* and is likely to be a relevant mechanism for the

selection of high affinity substrates by these kinases *in vivo*. The current view is that for substrate recognition, MAPKs first dock to the substrate through a binding interaction at one site leading to phosphorylation of the substrate at a second site at one or more Ser/Thr-Pro motifs. Recent studies demonstrate that the selective interaction of MAPK with substrates may influence the physiological regulation of MAPK targets *in vivo*. Examples of such docking interactions include the interaction of ERK or JNK with the transcription factor Elk-1. Furthermore, there is substantial evidence that the normal function of MAPK signaling modules requires the proper organization of their components within the cell.

Of interest, in the past decade, scaffolding proteins have emerged as general regulatory mechanisms ensuring the fidelity of intracellular pathways. These proteins bind components of signaling routes, physically organizing them to enable rapid physiological responses. The prototypical signaling scaffold is the yeast protein Ste5p which binds the components of the yeast MAPK cascade leading to the mating response after activation of the pheromone receptor, thus maintaining the signaling fidelity of this cascade. Several scaffold-binding components of MAPK cascades have now been described in multicellular organisms, including kinase suppressor of RAS (KSR) and c-Jun terminal kinase interacting protein family (JIP). Their role is to maintain the integrity of biochemical routes connecting cell surface receptors to the nucleus. For example, the JIP family of scaffolding proteins consists of three mammalian homologs JIP/IB-1, -1b, and -2. These molecules bind members of the mixed-lineage group of MAPKKK's (MLK) that have been reported to activate both JNK and p38. In addition, both IB1/JIP1 and IB2/JIP-2 have been found to bind the JNK MAPKK, MKK7, while IB2/JIP-2 has also been reported to bind MLK3 and p38 γ . An emerging concept derived from recent studies is that these scaffold proteins are organizers and keepers of signal specificity and fidelity. Indeed, it may be as important to keep signals separate between closely related MAPK cascades, as it is to integrate them in a coordinated response, particularly in gene expression control.

The activation of MAPK-mediated signaling pathways is often initiated by stimuli acting at the cell surface. However, many of the transcription factors that act as MAPK substrates are located in the nucleus, thus suggesting the existence of mechanisms by which the signals can be transmitted from the cytoplasm to the nucleus. This has been extensively investigated for the ERK1/2 pathway. For example, the activated forms of Raf (MAPKKK) are present at the plasma membrane, while activated MEK1 and MEK2 (MAPKK) are located in the cytoplasm, due to the presence of a nuclear export signal in the protein. Thus, the final step in signal transmission from the cytoplasm to the nucleus appears to be directly mediated by ERK1/2. Indeed, these ERKs are located in the cytoplasm of quiescent cells but in the nucleus of activated cells. The mechanism by which activation promotes the translocation of ERKs to the nucleus is still unclear. It has been suggested that ERKs may be actively sequestered in the cytoplasm by inactive MEK1/2, and upon their activation by Raf, MEK1 and MEK2 may dissociate from ERK1 and ERK2, which may then be able to migrate to the nucleus as homodimers. Whereas available evidence supports this model, it is still unclear whether the release of ERKs from their MAPKK,

MEK1, and MEK2 is sufficient to promote the nuclear accumulation of ERKs or whether additional processes are involved. Furthermore, whether other MAPKs use similar or distinct mechanisms to ultimately phosphorylate nuclear proteins is also poorly understood, and under current intense investigation.

Regulation of Gene Expression through MAPK Signaling Pathways

Although MAPKs can phosphorylate cytoplasmic substrates, most MAPK signaling pathways ultimately converge in the nucleus to regulate gene expression, either by acting at the pre-transcriptional, transcriptional, or posttranscriptional level. The most widely used mechanism by which MAPKs regulate gene expression is the phosphorylation of transcription factors, thereby enhancing their activity. For example, phosphorylation of the transcriptional activation domains of ATF2, CHOP, Elk-1, and c-Jun causes increased transcription. As studied in detail for the transcription factor CREB, transcription factor phosphorylation can cause changes in the interaction with co-activator molecules, including CBP and p300, which function, in part, through the regulation of the chromatin structure by acetylating histones.

Less frequent cases are found where MAPKs negatively regulate transcription factors by promoting their retention in the cytoplasm upon phosphorylation, and active dephosphorylation of these factors is then needed for their migration to the nucleus to stimulate gene transcription. As examples, phosphorylation of the transcription factors SMAD1 and NFAT4 by ERK1/2 and JNK, respectively, causes their cytoplasmic retention and therefore the inhibition of their transcriptional activity. Whether instead the phosphorylation by MAPKs of cytoplasmic transcription factors may cause their nuclear translocation is still unclear. Regulation of the DNA-binding activity is also a mechanism employed by MAPKs to control transcription factor activity. An example is the transcription factor Elk-1, which is phosphorylated by ERK, JNK, and p38 MAPKs leading to increased DNA binding.

Regulation of translation represents a fourth mechanism of regulation of gene expression by MAPKs. The best example is the translational regulation of cytokine expression observed in macrophages exposed to endotoxin. In this case, p38 MAPK acts on a *cis*-acting element in the tumor necrosis factor α (TNF α) messenger RNA (mRNA) to regulate its translation. Modulation of mRNA processing and nuclear export has not been described, although these biosynthetic steps also represent potential sites for intervention by MAPK.

The final mechanism employed by MAPK to regulate gene expression is the regulation of protein degradation. This is exemplified by the short-lived transcription factor c-Jun, which is rapidly degraded by the ubiquitin-proteasome pathway. Phosphorylation of c-Jun by JNK inhibits the ubiquitination of c-Jun and, therefore, its rapid degradation. Consequently, JNK activation prolongs the half-life of c-Jun, leading to the accumulation of the c-Jun protein. The regulation of protein stability by MAPK therefore contributes to the regulation of gene expression mediated by these signaling pathways.

Glossary

Centrosome Structure present at the spindle poles in many animal cells that is composed of a pair of centrioles and associated pericentriolar material.

Congression The motion of chromosomes to the midplane, or equator, of the spindle during prometaphase.

Kinetochores Structure located at the centromere of each chromatid that functions to link the chromosome to

the spindle. The kinetochore is also the location of components of the spindle assembly checkpoint.

Microtubule Polar, cytoskeletal polymer composed of tubulin dimers that are a major structural element of the mitotic spindle and are required for chromosome motion.

Spindle flux Poleward motion of microtubule polymers that occurs during metaphase and anaphase of mitosis.

Spindle Structure

The mitotic spindle at metaphase is a bilaterally symmetric, microtubule-based structure with chromosomes aligned in the middle. The spindle is bipolar: two spindle poles define the spindle axis and are the sites to which the chromatids are moved during anaphase (Figure 1). In many animal cells, a centrosome composed of a pair of centrioles and associated pericentriolar microtubule-nucleating material is present at the spindle poles (Figure 1). The major structural elements of the spindle are microtubules, dynamic cytoskeletal filaments that radiate from the two spindle poles. Microtubules attach chromosomes to the spindle and are essential for chromosome motion. Spindle microtubules are classified by their location in the spindle (Figure 1). Interpolar microtubules extend from each spindle pole and overlap in the middle of the spindle. Kinetochore microtubules have one end embedded in a specialized attachment site on the chromosome, the kinetochore. Astral microtubules extend away from the centrosomes toward the cell cortex and contribute to spindle positioning and in defining the position of the contractile ring at cytokinesis.

Considerable variation in spindle structure exists among diverse cells. In cells of higher plants, the spindle pole lacks centrioles and is broad, not focused. Plant spindles are also anastral, lacking astral microtubules. In yeasts, which undergo closed mitosis inside of an intact nuclear envelope, a spindle pole body is present at the two ends of the spindle. The spindle pole body, a trilaminar plaque-like structure embedded in the nuclear envelope, nucleates microtubules that radiate into the nucleus and cytoplasm. The number of spindle microtubules also varies among cell types. Yeasts have a simple spindle, and a single microtubule links each kinetochore to the spindle pole body. By contrast, typical animal cells have approximately 20 microtubules associated with each kinetochore and hundreds of microtubules present in each half-spindle. Despite these differences in spindle structure, in all cases mitosis accomplishes the accurate segregation of the replicated genetic material into the two daughter cells.

Phases of Mitosis

Prophase

Chromosome condensation

During the S (synthetic) phase of interphase, each chromosome is replicated resulting in two identical sister chromatids that are bound together by protein complexes called cohesions. Sister chromatids are very long strands of DNA that must be compacted for division. This process, called chromosome condensation, occurs by specialized proteins called condensins that coil the DNA into loops. As prophase progresses, the chromosomes become increasingly visible in the nucleus, first as threads or strands and later as highly condensed rod-like structures called chromosomes, each of which is composed of the two sister chromatids (Figure 2). The term mitosis comes from the Greek word *mito* meaning thread, referring to the appearance of thread-like structures in the prophase nucleus.

Kinetochore assembly

In order for the chromatids to be accurately segregated into the two daughter nuclei, they must be attached to, and later moved by, the spindle machinery. Mitotic chromosomes are characterized by an indentation, or primary constriction, called the centromere (Figure 1). The centromere is a region of highly repeated DNA sequences that serves as the assembly site for a plate-like structure called the kinetochore. The kinetochore functions to link each chromatid to the spindle via kinetochore microtubules and also functions as a signaling device that regulates progression through the cell cycle. Kinetochores of sister chromatids are arranged back to back so that the binding sites for spindle microtubules face in opposite directions to facilitate the association of each chromatid with microtubules from opposite spindle poles.

Centrosome separation

In animal cells, the centrosome is also duplicated during S phase of interphase, and the two daughter centrosomes remain adjacent to one another. Centrosome duplication ensures that two centrosomes are present at the beginning of

Figure 1 Highly schematic diagram of a bipolar mammalian mitotic spindle at the metaphase stage of mitosis. Microtubules are depicted as dark blue lines; interpolar, kinetochore, and astral microtubules (MTs) are labeled. The plus and minus ends of the microtubules are marked. Each pole has microtubules radiating from a centrosome (light blue). Contained within the pericentriolar microtubule-nucleating material (light blue) are two centrioles (orange). Examples of chromosomes, with sister chromatids in red and kinetochores in green, are shown aligned at the metaphase plate.

Figure 2 Phase-contrast light micrographs of LLC-PK1 mammalian cells in mitosis. Each panel shows a different cell at the indicated stage of mitosis.

mitosis to form the spindle poles and guarantees that each daughter cell inherits one centrosome. In prophase, the duplicated centrosomes separate and begin moving to opposite sides of the nucleus to establish a bipolar spindle. The microtubule-nucleating capacity of each centrosome also increases dramatically at prophase.

Prometaphase

Nuclear envelope breakdown

In cells that undergo open mitosis, the breakdown of the nuclear envelope marks the beginning of prometaphase. Microtubules assist nuclear envelope breakdown resulting in

the fragmentation of the nuclear membrane into small vesicles and consequently the release of the chromosomes into the cytoplasm.

Spindle assembly

Spindle assembly involves a dramatic reorganization of microtubules into a functional bipolar array. This process requires dynamic microtubules. Because microtubules are polar polymers, their two ends have different dynamic properties. The less dynamic end, called the minus end, is associated with the spindle pole material; the more dynamic end, called the plus end, extends outward toward the cell periphery (**Figure 1**). Microtubule plus ends display a behavior called dynamic instability, in which they switch stochastically between phases of assembly and disassembly. The result of dynamic instability behavior is that microtubule plus ends continually probe the cytoplasm as they grow and shorten. Microtubules in mitotic cells are more dynamic than microtubules in interphase cells; they switch from growing to shortening more frequently and shorten further before resuming growth. The result is a population of relatively short, highly dynamic microtubules that radiate from each spindle pole. At nuclear envelope breakdown, when the chromosomes are released into the cytoplasm, dynamic microtubules can interact with each kinetochore. Once a connection between a microtubule and kinetochore is established, the microtubule becomes less dynamic in order to maintain the connection. Cells monitor the attachment of chromosomes to the mitotic spindle and mitosis is delayed if even a single kinetochore is unattached. This regulatory system is called the spindle assembly checkpoint, or metaphase checkpoint.

Microtubule motor proteins, which utilize the energy of adenosine triphosphate hydrolysis to perform work in cells, are essential for assembling the bipolar spindle. The type and properties of the motor protein govern the direction of motion, either toward the minus end or the plus end of the microtubule. Multifunctional motors or motor protein complexes can exert force on microtubules by cross-linking neighboring microtubules and sliding them relative to one another or by

binding to one microtubule while walking along an adjacent one. Alternatively, the nonmotor region of the motor protein can bind to a tethered structure, the cell cortex for example, while the motor region of the protein applies a pulling force on the microtubule. Motor proteins are present at the kinetochores, between interpolar microtubules, along kinetochore microtubules and at the cell cortex.

Motor proteins contribute to various motions during mitosis. During centrosome separation in prophase, motors located between overlapping microtubules contribute to the separation of the two spindle poles. At the kinetochores, motors contribute to the initial attachment of chromosomes to spindle microtubules. Motors also contribute to congression, the movement of the chromosomes to the spindle equator following initial attachment. In the assembled spindle, a balance of the activities of oppositely directed motor proteins maintains spindle length; some motors tend to pull the poles together, and this force is resisted by motors that act to push the poles apart. Motor proteins also contribute to spindle positioning in mitotic cells, and to the dynamic turnover of mitotic microtubules.

Spindle assembly can also occur in the absence of centrosomes. In this situation, microtubules assemble in the vicinity of chromosomes and are subsequently sorted into a bipolar array by the activity of motor proteins. In both the presence and absence of centrosomes, dynamic microtubules and motor proteins contribute to spindle formation.

Metaphase

The cell is in metaphase when all of the duplicated chromosomes are aligned midway between the two spindle poles (Figure 2 and 3), a location referred to as the metaphase plate or spindle equator. Spindle length remains relatively constant at metaphase, but the spindle microtubules are not static. Rather, they undergo a behavior called spindle flux, in which spindle microtubules continually assemble at their plus ends and disassemble at the minus ends, coupled to poleward translocation of the polymer. As a result of flux, marks placed on spindle microtubules are observed to move slowly toward the poles during metaphase and anaphase of mitosis.

Not only are microtubules dynamic at metaphase, but the chromosomes are active as well, oscillating toward and away from each spindle pole. Chromosomes are also under tension, ready for subsequent movement in anaphase. If the connection between one sister chromatid and the pole is severed at metaphase, the chromosome moves to the pole to which it remains attached, demonstrating that the metaphase position results from a balance of pole-directed forces acting on the chromosomes.

Anaphase

During anaphase, sister chromatids separate and move to the spindle poles (Figures 2 and 3). Anaphase consists of two phases, anaphase A and B. During anaphase A, the chromosomes move to the poles and kinetochore fiber microtubules shorten; during anaphase B, the spindle poles move apart as interpolar microtubules elongate and slide past one another. Many cells undergo both anaphase A and B motions, but, in some cases, one or the other motion dominates.

Figure 3 Distribution of microtubules throughout mitosis. Fluorescence light micrographs of cells that have been fixed and stained with antibodies to tubulin, to label microtubules, shown in green. Images are maximum projections of deconvolved image stacks taken with a spinning disk confocal microscope.

Separation of the paired sister chromatids is required for poleward motion in anaphase. Chromatid separation results from the proteolytic degradation of components that link the chromatids at the centromere. Degradation is triggered by the activity of the anaphase-promoting complex, which regulates cell-cycle progression. Chromatid separation is not the result of tugging by microtubules and motor proteins, and can be observed even in the absence of microtubules.

Although the motion of the chromosomes to the spindle poles in anaphase has fascinated biologists for many years, the molecular basis for this motion remains controversial and incompletely understood. During anaphase A, kinetochore microtubules must shorten as the chromosomes move poleward. Measurements of spindle flux show that subunit loss from microtubules occurs at the spindle poles during anaphase. In many cells, however, the rate that chromosomes move exceeds the rate of subunit loss at the pole, and, thus, subunit loss must also occur at the kinetochore.

Pioneering studies of mitosis in living embryonic cells demonstrated that assembly and disassembly of microtubule polymers result in chromosome motion. This work led to the hypothesis that microtubule disassembly drives chromosome motion. Later work identified molecular motors at the kinetochore, leading to the alternative hypothesis that forces generated

by molecular motors drive chromosome motion. One possibility is that molecular motors power chromosome motion, but kinetochore microtubule disassembly limits the rate of chromosome motion. Alternatively, disassembly may be responsible for chromosome motion, and motors may tether the chromosomes to the shortening fiber. The presence of potentially redundant mechanisms for chromosome motion may reflect the fact that mitotic fidelity is of utmost importance.

Telophase

In telophase, the chromosomes decondense, and the nuclear envelope begins to reform around them (Figures 2 and 3), returning the cell to the interphase condition. The short dynamic microtubules of the spindle are replaced with the less-dynamic microtubules of the interphase array that extend to the cell periphery. During telophase, the contractile ring assembles midway between the spindle poles in preparation for cytokinesis.

Cytokinesis

Cytokinesis is the process of constricting the cytoplasm between the two forming daughter nuclei resulting in the formation of two cells (Figures 2 and 3). Cytokinesis is achieved by a contractile ring, or belt, composed of filaments of the cytoskeletal polymer, actin, and the molecular motor protein myosin II, which provides the force for cytokinesis. The contractile ring is tethered to the cell membrane, and its contraction creates a cleavage furrow, or indentation of the plasma membrane, during cytokinesis. The contractile ring assembles midway between the two spindle poles in telophase, and disassembles when cytokinesis is completed. The signals that determine the location of contractile ring formation in the cell cortex are incompletely understood, but it is

well-established that microtubules are involved in their delivery to the cortex. In some cells, radiating astral microtubules that overlap midway between the spindle poles dictate the site of contractile ring formation. In other cases, interzonal microtubules located between the separating chromosomes play an important role in specifying the location of furrow formation. The completion of cytokinesis marks the end of mitosis and the birth of two completely independent daughter cells in interphase of their cell cycle.

Glossary

Catalytic intermediate Chemical species that transiently forms during an enzymatic reaction.

Introduction

The human genome encode for two enzymes, monoamine oxidase A and B (MAO A and MAO B), that catalyze the oxidation of a number of amine-containing molecules. The two proteins are encoded by different genes although they have significant (about 70%) sequence identity. This similarity is matched by partly overlapping substrate specificities. In very general terms, MAO A accepts bulkier substrates than MAO B. This distinction can be best illustrated by the two neurotransmitters dopamine and serotonin; dopamine is a good substrate for MAO B whereas serotonin is the preferred substrate for MAO A. The main reason for the huge number of studies on MAOs resides in their pharmacological relevance. It was found already in the fifties that these enzymes represent valid targets for the treatment of neurological disorders; more specifically, depression and Parkinson's disease. In this article, we first describe the reaction catalyzed by MAOs. Next we discuss the inhibitors and drugs targeting these proteins in light of the more recent biochemical and structural studies.

Reaction Catalyzed

Human MAOs are typical flavin-dependent oxidases. They use a flavin-adenine dinucleotide (FAD) cofactor to catalyze the oxidation of the amine group of the substrate. FAD is covalently bound to a protein Cys residue and the formation of the covalent bond, as in most covalent flavoenzymes, is self-catalyzed – that is, it does not require the action of an external protein or cofactor. The enzymes take advantage of the redox properties of the flavin to perform the oxidation of the substrate $-CH_2-NH_2-$ to convert it into the corresponding imine (Figure 1). This compound spontaneously hydrolyzes to the aldehyde, which is, therefore, the final reaction product. Substrate oxidation leads to the formation of the two-electron-reduced flavin which needs to be re-oxidized. As it ought to be in oxidases, the electron acceptor is oxygen which is converted to hydrogen peroxide, the other reaction product. Normally, it is thought that the enzyme functions according to a ternary complex mechanism – that is flavin re-oxidation takes place when the imine product is not yet released by the enzyme. Indeed, the imine, at least for certain substrates, is known to enhance the reactivity of the reduced enzyme with oxygen. It is beyond the scope of this article to discuss the intricacies and the huge body of literature concerning the mechanism of substrate oxidation/flavin reduction. The

interested reader is referred to the reference list at the end of the article. Here, we simply summarize the state of the art about this hotly debated subject in the enzymology community. In essence, there are three proposals: the substrate is oxidized through a transient covalent intermediate with flavin; substrate oxidation takes place through direct transfer of a hydride anion from the carbon atom of the $-CH_2-NH_2-$ unit to the flavin; oxidation occurs through stepwise transfer of electrons and/or hydrogen atoms with transient formation of a radical intermediate. Future work is required to determine which of these mechanistic proposals will finally prove to be the correct one.

Cellular Localization

An important feature of MAOs is that they are membrane bound. Indeed, both MAO A and MAO B feature a C-terminal hydrophobic tail that, as initially predicted by sequence analysis and later confirmed by the crystal structures, forms a trans-membrane helix that anchors these dimeric enzymes to the outer mitochondrial membranes. The physiological significance of this localization remains unclear. At present, it is also unknown how the proteins are oriented in the membrane. Two possibilities exist; the globular domain region of the protein (Figure 2) is located in the space between the inner and outer membranes of the mitochondrion or the globular domain is exposed on the mitochondrial outer surface. Biochemical studies have shown that removal by protein engineering of the membrane-binding regions lead to a more water-soluble protein that retains catalytic activity but it is far less stable. A fascinating speculation is that the membrane localization might favor substrate binding. The idea is that the negatively charged membrane surface would attract the positively charged amine substrates which, as gathered from the crystal structures, enter the active site through a gating loop located at the protein–membrane interface (Figure 2).

Enzyme Substrates

Both MAO A and MAO B are rather promiscuous and known to accept a variety of substrates. The two enzymes feature internal cavities located in front of the flavin cofactor. These cavities exhibit different shapes on their rear side as consequence of a few critical amino acid differences which result in only partly similar substrate specificities. Both proteins are able to act on small aromatic amines such as benzylamine (Figure 1 and

Figure 1 Scheme of the reaction catalyzed by MAOs with reference to the benzylamine substrate and of the covalently protein-bound flavin.

Figure 2 Schematic illustration derived from the crystal structure analysis of the human MAO B dimer bound to the outer mitochondrial membrane. The substrate-binding domain is in blue, the flavin-binding domain in red. The membrane-bound helices are in green. At the membrane–protein interface is located a loop that represents the entry point for the substrate into the active site, located in front of the flavin cofactor (yellow). In black is shown diphenylbutene, a MAO B inhibitor that binds in the enzyme active site.

Figure 3) but differences arise when larger molecules are considered. Thus, serotonin is a preferential substrate for MAO A whereas dopamine is a better (but not exclusive) substrate for MAO B. The enzymes are also able to act on various xenobiotics. A well-known example is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This is a horribly potent neurotoxin that was initially discovered as contaminant in certain synthetic preparations of illicit drugs. MPTP is oxidized by MAO B becoming an incredibly effective toxin that in matters of hours causes a syndrome very similar to the Parkinson's

disease. Consistently, MPTP has become a widely used chemical tool to generate the disease in animal models. Another example of a peculiar substrate is the amine analog of the hydroxyl group of farnesol, an aliphatic compound that can be oxidized (though not very effectively) by MAO B.

Inhibition and Pharmacology

Because of their key role in the regulation of neurotransmitter levels, MAOs were soon discovered to be valuable targets for the treatment of neurological disorders. The existence of a tyramine oxidase activity was reported in a groundbreaking paper by Hare in 1928. Less than 30 years later, the first MAO inhibitors were reported. It is interesting to remember how these inhibitors were discovered by Zeller and coworkers. The discovery came from the observation that tuberculosis patients receiving isoniazid (isonicotinylhydrazine) therapy experienced mood elevation and, thus, phenylethylhydrazine was developed for use as a MAO inhibitor (MAO-I) for the treatment of depression. This finding initiated an enormous research effort, which lasted for more than 40 years and led to the publication of no less than 15 000 scientific articles on MAO inhibition. These complex efforts culminated in the development (in the late fifties) of tranylcypromine (parnate), an antidepressant still in use. Further important milestones were the development of inhibitors of the so-called propargyl class (they feature a propargylamine group). Among them, deprenyl (selegiline) and, more recently, rasagiline are proving to be an effective drug for the therapy of Parkinson's disease. The rationale for MAO B inhibitors as anti-Parkinson agents is that they increase dopamine levels by blocking MAO-mediated neurotransmitter degradation. This effect should counteract the reduced dopamine levels caused by the progressive degeneration of dopaminergic neurons. An additional effect is thought to be caused by the antioxidant effect of MAO-Is which block key and very active oxidative enzymes such as MAOs. An important point to be made is that these anti-MAO drugs are all covalent inhibitors that, upon binding,

Figure 3 Chemical formulas of MAO A and/or MAO B substrates.

Figure 4 Chemical formulas of the adduct formed by the MAO B flavin with rasagiline, a recently approved anti-Parkinson drug.

react with the flavin forming a covalent adduct (Figure 4). Furthermore, most of these drugs are not very selective because they inhibit (though with different efficacies) both MAO A and B, and, as reported more recently, certain histone demethylases (LSD1 and LSD2) which share weak similarities with MAOs. In pharmacological terms, this lack of selectivity and mode of inhibition is reflected in significant side effects often exhibited by MAO-Is. Patients taking these drugs must monitor their blood pressure and pay attention to their diet, avoiding food that are rich in amines (the so-called cheese effect). At present, a handful of noncovalent highly selective MAO inhibitors are in advanced clinical trials and promise to be very effective for the solution of at least some of these problems.

MAO and Behavior

In recent years, MAOs have been making headlines in newspapers. The reason is that a few studies have linked genetic abnormalities in MAO A expression and activities to aggressive behavior – a MAO A gene has been described as the ‘warrior

gene’. The rationale is that low levels of MAO A activity can lead to increased levels of serotonin, enhancing the propensity to an aggressive and violent behavior. This idea originated from the genetic analysis of a Dutch family with a history of violence. It is of interest to note that this problem is expected to affect only males because both MAO genes are located on the X chromosome. Obviously, this is a hotly debated and highly controversial topic. Although it is hard to imagine that behavior can be simply linked to a single gene alteration, it remains possible that deficiencies in MAO function might affect central nervous system (CNS) activity by modifying neurotransmitter levels. However, this area needs many more studies. It is clear that after 80 years since their discovery, MAOs are likely to remain under the spotlight.

mRNA Polyadenylation in Eukaryotes

J L Manley and D C Di Giammartino, Columbia University, New York, NY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Capping The process by which a 7-methyl guanosine is added to the 5' end of a precursor-messenger RNA (pre-mRNA) by a 5' to 5' triphosphate linkage. 5' Capping is important for regulation of mRNA nuclear export, prevention of degradation by exonucleases, promotion of translation, and 5' proximal intron excision.

Messenger ribonucleic acid (mRNA) A molecule transcribed from DNA by an RNA polymerase. Mature mRNAs contain 5' and 3' untranslated regions (UTRs), a modified base at the 5' end called 'cap', a polyA tail at the 3' end, and a protein-coding region in between. mRNAs are exported to the cytoplasm where they will be translated into a polymer of amino acids which constitutes a protein.

Polyadenylation The process by which poly(A) polymerase (PAP) adds an unencoded poly(A) tail at the 3' end of a maturing mRNA. The site for poly(A) addition is created by a large protein complex that cleaves the pre-mRNA at the polyadenylation site in the 3' UTR. More than one

polyadenylation site might be present allowing a single gene to encode multiple transcripts with distinct 3' ends, an event called 'alternative polyadenylation'.

Splicing It is a two-step reaction that leads to the removal of an intron and the joining of two adjacent exons. The spliceosome is the large complex that directs this step of pre-mRNA maturation and is made of approximately 200 proteins and five small RNAs.

Transcription The process by which an RNA polymerase synthesizes an RNA molecule on a DNA template. In eukaryotes, there are three RNA polymerases, but only RNA polymerase II is responsible for transcription of protein-coding genes into mRNA.

3' UTR The untranslated region at the 3' end of an mRNA, after the stop codon. It includes regulatory regions such as those that direct cleavage and polyadenylation as well as sequences that regulate mRNA translation and stability by serving as binding sites for microRNAs or regulatory proteins.

Introduction

Eukaryotic precursor-messenger RNAs (pre-mRNAs) must undergo several processing events before the mature mRNA can be transported out of the nucleus and translated into proteins. Transcription, capping at the 5' end, splicing of introns, and polyadenylation of the 3' end are all complex reactions that require numerous proteins (and in the case of splicing, RNAs). Interestingly, these reactions have all been found to be interrelated, such that proteins involved in one step often also participate in the other/s. It is the accurate sequence of events of this highly regulated process that leads to the formation of an mRNA.

All eukaryotic pre-mRNAs, with the exception of replication-dependent histone transcripts, acquire a polyadenylate tail at their 3' end. The maturation of the 3' end of the pre-mRNA is achieved by a two-step reaction that involves an endonucleolytic cleavage of a phosphodiester bond in the pre-mRNA transcript, followed by addition of a polyadenylate tail on the upstream cleavage product, which corresponds to the mature mRNA. In order for these events to occur, four multi-subunit protein complexes, with additional accessory factors, have to bind specific RNA sequences that are found in the primary transcript, and this dictates the precise site where cleavage will occur. The importance of this step is emphasized by the absolute requirement of genes encoding 3' processing factors for cell viability in yeast and higher eukaryotes, and by the association of some human diseases with aberrant polyadenylation events. Such diseases can be caused either by mutations in the *cis*-acting RNA sequences or by mutations/deregulation of the *trans*-acting protein factors involved.

Polyadenylation is a fundamental step of gene expression and its success will determine many aspects of mRNA metabolism: transcription termination by RNAP II (which occurs past the polyadenylation site and has been shown to be dependent on the 3' processing), mRNA stability, mRNA export to the cytoplasm, and the efficiency of translation of the mRNAs into proteins are all dependent on 3' processing. Therefore, the effectiveness by which the 3' protein complex assembles onto defined sequence elements in the 3' untranslated region (UTR) will determine the final level of protein expression.

Recent studies indicate that more than 50% of human genes encode transcripts that contain multiple polyadenylation sites. These alternative sites either can be found in internal introns and therefore alternative polyadenylation will be coupled to alternative splicing events, producing different protein isoforms, or can all be in the 3' UTR, resulting in transcripts encoding the same protein but with 3' UTRs of different length. The length of the 3' UTR can, in turn, affect the stability, localization, transport, and translational properties of the mRNA. Interestingly, differential processing at multiple poly(A) sites can be influenced by physiological conditions such as differentiation and development, or by pathological events such as cancer and viral infection.

RNA Sequences That Direct Cleavage and Polyadenylation

In mammalian cells, three *cis*-elements define the cleavage site. The highly conserved hexanucleotide AAUAAA is found 10–30 nucleotides (nt) upstream of the cleavage site. Extensive

Figure 1 A schematic model of the mammalian pre-mRNA 3'-end processing machinery.

mutagenesis analysis and naturally occurring mutations have proved that this sequence is essential for both cleavage and specific polyadenylation. Variants of the AAUAAA motif are usually associated with alternatively used poly(A) sites.

The second motif of the core polyadenylation signal is the downstream element (DSE), which is located within 30-nt downstream of the cleavage site and consists of a U-rich or/and a GU-rich sequence in the form of YGUGUYY (Y = pyrimidine). This sequence is poorly conserved and mutations or small deletions have only a weak effect on the efficiency of 3' processing.

The cleavage site will be determined by the distance between the AAUAAA and the DSE. The sequence where cleavage will occur is not conserved, but, in 70% of the cases, is located immediately after an adenosine residue that is very often preceded by a cytosine residue. In addition to these three core polyadenylation sequences, an upstream (located upstream of the AAUAAA) and/or downstream (located after the DSE) auxiliary element are sometimes present: the first is a U-rich sequence while the second is a G-rich sequence, but these are very poorly conserved.

In yeast, the RNA signals that direct polyadenylation are different from those used in higher eukaryotes in both sequence and organization and appear to be much less conserved. The yeast poly(A) site is defined by four elements: the AU-rich efficiency element, the A-rich positioning element, the actual cleavage site, and the U-rich elements positioned upstream and downstream of the cleavage site.

Protein Complexes Involved in 3' Processing

The development of appropriate techniques to reproduce the cleavage and polyadenylation reactions *in vitro*, by using cell extracts and *in vitro*-transcribed pre-mRNAs, allowed the

biochemical characterization of the proteins involved in 3'-end maturation of pre-mRNAs.

Two processes as simple as cleavage and polyadenylation, which could be catalyzed by the action of only two enzymes (an endonuclease and a poly(A) polymerase (PAP)), are in fact supported by a vast number of protein factors (**Figure 1**) emphasizing the necessity to finely regulate the process and to coordinate it with other nuclear events.

The core molecular machinery responsible for 3' end formation in mammals includes four multi-subunit protein complexes: cleavage and polyadenylation specificity factor (CPSF), cleavage stimulation factor (CstF), cleavage factor I (CFI), and cleavage factor II (CFII). In addition, PAP, symplekin, poly(A)-binding protein II (PABPII), and the C-terminal domain (CTD) of the RNA polymerase II largest subunit are also part of the core machinery. Other proteins have been discovered in a recent proteomic study to associate with the core factors and are very likely to be part of the multi-subunit complexes mentioned above; although they are annotated in **Table 1**, they will not be discussed here, due to the lack of enough published data on their function.

Mammalian CPSF contains five subunits (CPSF-160, CPSF-100, CPSF-73, CPSF-30, and Fip1), which are all essential for efficient cleavage and polyadenylation. The CPSF complex binds to the AAUAAA sequence, mainly through CPSF-160, but the interaction with the RNA is greatly enhanced by cooperative binding between CPSF and CstF. CPSF-160 is known to bind CstF-77 and PAP, and it also associates with proteins involved in transcription initiation (TFIID) and elongation (PolII CTD). CPSF-73 has recently been reported to be the actual endoribonuclease, responsible for the cleavage at the poly(A) site, but it is the entire 3' processing complex that defines the exact cleavage site and confers sequence specificity. CPSF-73 contains a metallo- β -lactamase domain and is the founding member of the β -CASP protein superfamily.

Table 1 Characteristics of the protein factors of the mammalian pre-mRNA 3'-end processing complex

<i>Protein factor (processing step)</i>	<i>Subunits</i>	<i>Yeast homologue (sub-complex)</i>	<i>Sequence characteristics</i>	<i>Protein function</i>	<i>Interacting proteins</i>
CPSF (cleavage and polyadenylation)	CPSF-160	Cft 1p/Yhh1p (CPF)	Three possible β -propellers	Binds the AAUAAA sequence	CstF-77, Pol II CTD, PAP, Fip1, TFIID CPSF-73 CstF-64 symplekin CPSF-100, CstF64, symplekin Fip1 PAP, CPSF-160, CPSF-70, CstF-77
	CPSF-100	Cft2p/Ydh1p (CPF)	Non-metal binding β -lactamase domain

	hClp1		Walker A and B motifs for ATP binding	Tethers CPSF with CF Im	
Symplekin (cleavage)	Pcf11	Pcf11p (CFIA)	polII CTD interacting motif, two zinc fingers	Mediates interaction between CPSF and CstF Catalyzes the addition of the poly(A) tail to cleaved mRNA, non specific activity by itself	CstF, CPSF. Ssu72, pol II CTD CPSF-160, Fip1, CFIm
PAP (cleavage and polyadenylation)		Pta1p (CPF)	HEAT fold		
		Pap1p	Catalytic core at N-terminus, C-terminus contains RBS, bipartite NLS, ST-rich region		
PABPII (polyadenylation)		Pab1p	Two RRM domains	Responsible for processive elongation and control of poly(A) tail length, stabilizes the tail by binding	CPSF-30
Pol II CTD (cleavage)		Pol II CTD	YSPTSPS repeats (52 in humans)	Essential for co-transcriptional recruitment of CPSF and CstF and for cleavage	CPSF-160, CstF-77, CstF-50, Pcf11
PP1 (polyadenylation)		Glc7p	RS domain, RING finger, zinc knuckle, DWNN, pro-rich	Type 1 protein phosphatase	p53, Rb
RBBP6		Mpe1p (CPF)			

CstF consists of three subunits (CstF-77, CstF-64, and CstF-50), which are necessary for cleavage but not for polyadenylation. CstF-64 contains a typical RNP-type RNA-binding domain (RBD) that binds to the G/U-rich element in the mRNA precursor. In addition, it contains 12 repeats of a pentapeptide motif, MEAR(A/G), the function of which is unknown. In humans, a second isoform, known as tCstF-64, exists. CstF-77 contains a half A TPR (HAT) motif, which mediates its homodimerization. Both CstF-77 and CstF-50 bind specifically to the CTD of Pol II but the latter does so with higher efficiency. The WD-40 repeats in CstF-50 are involved in its interaction with CstF-77. CstF-50 was found to interact by yeast two-hybrid screen with breast cancer 1 (BRCA1) associated ring domain (BARD1), a protein associated with the tumor-suppressor BRCA1. Interestingly, the CstF/BARD1/BRCA1 complex is stabilized under conditions of DNA damage, leading to inhibition of 3' processing (see below for more details). CFI and CFII are required only for the cleavage reaction. The former is a heterodimer made up of CF-25 and one of three related subunits of 59-, 68-, or 72-kDa subunits; its primary function is to provide additional recognition of the pre-mRNA and aid the definition of the proper polyadenylation site. In addition, CFI-68 has recently been reported to be involved in mRNA export to the cytoplasm. CFII also consists of two subunits, Pcf11 and Clp1. Interestingly, Pcf11 has a PolII CTD-interacting domain (CID), and mutations in this domain cause incorrect transcription termination.

PAP is the polymerase responsible for the addition of the poly(A) tail to the cleaved mRNA. Several isoforms of this protein have been reported to arise from the same gene, with PAPII (referred here as PAP) being the predominant nuclear species in most cells. Two additional nuclear poly(A) polymerases transcribed from different genes are of particular interest: neo-PAP, which is overexpressed in human tumors and star-PAP, which is required for the polyadenylation of a group of genes encoding proteins involved in detoxification and/or oxidative stress response. PAP interacts with CPSF160, Fip1, and CF-25. Its N-terminal domain coordinates two metal ions (Mg or Mn) that are required for catalysis, while the CTD is subject to extensive posttranslational modifications that modulate PAP's activity (see below). CPSF and PAP are sufficient for poly(A) addition to a pre-cleaved RNA substrate but rapid elongation and control of poly(A) length (up to 200–300 bases in mammals) requires PABPII. In mammalian cells, PABPII binds nascent tracts of adenylate residues and, along with CPSF, stimulates PAP to switch from distributive synthesis to processive synthesis.

Symplekin is thought to function as a scaffold in the 3' processing complex. Recently, it has also been found to associate with a CTD phosphatase, Ssu72, and to stimulate its catalytic activity. Significantly, this interaction appears to be required for transcription-coupled polyadenylation, but not for polyadenylation of a presynthesized substrate.

The CTD is also required for efficient cleavage *in vitro*. In humans, the heptapeptide YSPTSPS is repeated 52 times and is subject to extensive phosphorylation events that are specific to transcriptional stages. One of these, phosphorylation of the ser 2 position, can enhance 3' processing *in vivo*. As mentioned earlier, several 3' processing factors can associate with

Pol II CTD at the promoter and remain associated during transcription.

The yeast 3' processing complex shares some similarities with the mammalian complex, reflected in a high number of homologous proteins, but the overall complex composition is different. The yeast sub-complexes include the cleavage factor IA (CFIA), cleavage factor IB (CFIB), and cleavage and polyadenylation factor (CPF). The latter, in turn, is composed of CFII and polyadenylation factor I (PFI). CFII and PFI contain subunits that are homologous to the mammalian CPSF, while the CFIA complex shares homologous subunits with mammalian CFII and CstF.

Regulation of mRNA 3' End Formation

One way to regulate cleavage and polyadenylation of pre-mRNA is through posttranslational modification of the 3' processing factors. Importantly, all types of modifications that will be mentioned are covalent but reversible, such that they provide an efficient but temporary way to control gene expression. Some of these modifications are cell-cycle dependent, such as PAP's phosphorylation, while others are triggered by environmental conditions such as stress and DNA damage. Phosphorylated serine, threonine, and, to a lesser extent, tyrosine residues have been detected within the core 3' processing proteins, either by phosphoproteomic screens or by specific biochemical studies. The most explicative example is the cell-cycle-dependent phosphorylation of PAP. During mitosis, PAP is hyperphosphorylated by Cdc2/Cyclin B, which reduces its enzymatic activity, contributing to a general repression of mRNA and protein production during mitosis. Another important posttranslational modification is sumoylation of lysine residues. Proteins modified by small ubiquitin-like modifier (SUMO) are CPSF-73, symplekin, and PAP. This modification was shown to enhance formation of the 3' processing complex as well as the nuclear localization of PAP. Other modifications include lysine acetylation in PAP and CFI25 and methylation of arginine residues in CFI68, although the functional significance of these is unclear.

Posttranslational modifications can regulate the formation of the 3' end of pre-mRNAs by different mechanisms: modification of a protein can interfere with its binding to the rest of the complex, and the absence of that particular protein may, in turn, lead to destabilization of the whole complex, as is the case for sumoylation. Conversely, a posttranslational modification may also lead to recruitment of a binding partner that would not otherwise be associated with the complex. An additional possibility is that the modification leads to a conformational change or a change in the charge of the protein that inhibits the binding of the protein to the mRNA. Some types of modifications, such as sumoylation, are well known to regulate the localization of the modified proteins and affect the nucleo-cytoplasmic shuttling, while others can lead to degradation of the target, for example, in the presence of DNA damage, for example, after UV treatment, the CTD will be ubiquitinated by a pathway involving BRCA1/BARD1, which are recruited to the site of RNA processing by CstF-50. Ubiquitination of CTD causes its proteosomal

degradation, leading to inhibition of transcription. These events would also inhibit the cleavage of pre-mRNA, since the 3' processing factors cannot be recruited properly without the CTD.

In the past 10 years, it has become increasingly evident that usage of alternative poly(A) sites is a common mechanism to regulate gene expression. Fifty percent of human genes encode multiple transcripts derived from alternative polyadenylation. In many mRNAs, the choice of the site changes in response to physiological conditions such as cell growth, development, and differentiation, while in other cases it is triggered by external conditions such as cancer and viral infection. Alternative polyadenylation may or may not be affected by splicing, depending on if the alternative site is present in an intron or in the 3' UTR. A classical example of an alternative polyadenylation is the IgM heavy chain expression, in which increased accumulation of CstF in plasma cells is sufficient to switch the heavy chain from the membrane-bound form to the secreted form during differentiation of B lymphocytes.

Several recent reports have examined alternative polyadenylation using microarray-based techniques and found a general correlation between 3' UTR shortening and cell proliferation and transformation, while there is a preferred usage of distal poly(A) sites during differentiation. 3' UTR shortening can have striking functional consequences, for example, a shorter transcript produces more protein, an effect that can be explained by the absence of inhibitory sequences, such as miRNA-binding sites or other destabilizing elements that would otherwise be present in the longer transcript. The length of the 3' UTR might affect not only the stability but also the localization, transport, and translational properties of the mRNA. The mechanisms that regulate such global events are mostly unknown and intense research is currently being carried out in order to better understand this phenomenon at the molecular level.

Coupling of 3' End Processing with Other Steps of Gene Expression

The maturation of the 3' end of pre-mRNA is closely connected to most steps of gene expression. Starting from transcription initiation, CPSF was first found to associate with TFIID and later, both CPSF and CstF were shown to be located at the transcription start site by chromatin immunoprecipitation experiments. These factors are believed to travel along the gene, during transcription elongation, through their interaction with the CTD. Once the polyadenylation signals are transcribed, the 3' processing factors associate with the signal sequences in the newly synthesized pre-mRNA. The connection with transcription does not end here. Indeed, transcription termination is dependent on the molecular machinery responsible for 3' end formation, and an intact polyadenylation signal has long been known to be necessary for transcription termination of protein-coding genes in human and yeast cells. In the last 10 years, it became increasingly evident that not only transcription and mRNA maturation, but virtually all steps of gene expression are coupled processes that can regulate one another.

A link between splicing and 3' processing has been established by several studies. In one example, the splicing factor

U2AF65, by binding to the polypyrimidine tract at the last intron 3' splice site, stimulates both cleavage and polyadenylation by recruiting the CFI complex to the poly(A) site. The coupling is bidirectional, as evidenced by the fact that U2AF interaction with PAP stimulates splicing of the last intron. Another example of interconnection with the splicing machinery is through the splicing repressor polypyrimidine tract-binding protein (PTB). PTB can play a repressive role by competing with CstF binding to the DSE, but it can also have a stimulating function when associated to hnRNP H. In this case, PTB increases binding of hnRNP H to the G-rich auxiliary element, which in turn stimulates cleavage by recruiting CstF and PAP.

A poly(A) tail has also been proved to be important for an efficient translation of the mRNA into protein; in the cytoplasm the PABPs will facilitate the formation of a loop structure by interacting on one side with the poly(A) tail and on the other with the elongation initiation factor eIF4G, which in turn binds to the 5' cap of the mRNA, thereby forming a closed circle which enhances translation. Other essential functions of the poly(A) tail are to promote transport of mRNA from the nucleus to the cytoplasm and to enhance mRNA stability, by preventing the action of the exosome complex of 3'→5' exonucleases.

Studies over the past 20 years have identified numerous factors involved in pre-mRNA 3' end processing, but more research is needed to elucidate the functional properties of many of the new protein factors found to be associated with this complex, especially those that might connect cleavage and polyadenylation with other nuclear events. An extensive characterization of the cross talk between 3' processing and other cellular processes will be important for better understanding gene regulation on a global level.

Glossary

Autophagy A highly conserved process in which proteins and other macromolecules, or even whole organelles, can be degraded. Their components may be recycled to provide building blocks for anabolic processes and/or metabolic energy. Autophagy may also remove damaged cellular components. In autophagy, regions of the cytoplasm are first engulfed by a membrane to form autophagosomes, which then fuse with endosomes or lysosomes, leading to the degradation of the contents. Autophagy also provides a way by which damaged cells can be eliminated.

GTPases Typically small monomeric proteins which bind guanosine triphosphate (GTP) and can hydrolyze it to guanosine diphosphate (GDP). In almost cases, the GTP-bound form of the protein is active, so GTP hydrolysis switches it off. Often, the GTPase activity of the protein is low and is enhanced by a GTPase-activator protein (GAP). Regenerating the active GTP-bound form may require a guanine nucleotide-exchange factor (GEF). Both the GAP and GEF can provide regulatory inputs to control the proportion of the GTPase that is in its active form.

Protein kinases Enzymes that transfer phosphate groups from adenosine triphosphate (ATP) onto specific amino acid residues in proteins. This modification often alters the properties of the protein and is a very widespread physiological mechanism for controlling protein function.

Rapamycin A chemical compound first isolated from the bacterium *Streptomyces hygroscopicus* found on Easter Island. The local name for this island is Rapa Nui, hence rapamycin. Rapamycin was first studied as an antifungal agent and was later shown to inhibit the proliferation of cells of the immune system.

Scaffold proteins Bind to other proteins and thereby mediate the assembly of protein:protein complexes, thereby acting to enhance the efficiency and specificity of intracellular signaling pathways.

Tuberous sclerosis Also termed tuberous sclerosis complex (TSC) is a rare genetic disease caused by mutations in the genes for the proteins TSC1 (hamartin) or TSC2 (tuberin). TSC patients develop benign tumors in the brain or other organs such as the kidneys, heart, lungs, or skin. Symptoms may include seizures, behavioral problems, skin problems, lung, and kidney disease; mTOR.

Introduction

Recent years have witnessed a tremendous increase in interest in the mammalian target of rapamycin (mTOR) and its roles in normal cell regulation and in disease. This reflects improved knowledge about this protein kinase and its cellular functions, in particular the control of its function; the cellular processes that it regulates; and its importance in disease. In several areas, including oncology, there is a high level of interest in devising ways to inhibit mTOR function for therapeutic reasons.

mTOR and mTOR Complexes

mTOR is a protein which is composed of several distinct domains (Figure 1). These include the so-called HEAT repeats, which generally mediate protein:protein interactions; an FRB (FK506 and rapamycin-binding domain); and a kinase domain. The kinase domain is similar to those found in lipid kinases of the phosphatidylinositol 3-kinase (PI 3-kinase) family, although mTOR phosphorylates proteins on serine or threonine residues, not lipids. The FRB domain interacts with a complex between a drug termed rapamycin and a small protein (an 'immunophilin') called FKBP12. The rapamycin-FKBP12 complex inhibits some of the actions of mTOR, but it is not clear how. mTOR also contains the so-called FAT and FATC domains

(Figure 1) which may mediate protein:protein interactions and confer control of mTOR function by cellular redox status, although this requires further study.

mTOR binds several other proteins and forms two distinct kinds of multiprotein complex in the cell. mTOR complex 1 (mTORC1) contains mTOR, a large scaffold protein termed raptor (regulatory associated protein of mTOR), and mLst8 or GβL. Raptor plays a key role on the function of mTORC1 by interacting with substrates and recruits them to be phosphorylated by this complex. Such substrates include the p70 S6 kinases, which contain a 5 amino acid TOS (for TOR signaling) motif (see Figures 1 and 2).

mTOR complex 2 (mTORC2) also contains mTOR and mLst8, but not raptor. Instead, it contains other proteins, including rictor (rapamycin-insensitive companion of mTOR), protor, and mSin1 (Figure 1). mTORC2 phosphorylates different protein substrates from mTORC1; rictor may act as a scaffold to recruit mTORC2's substrates as raptor does for mTORC1.

Studies in genetically modified mice have revealed the key importance of mTOR and raptor: knocking out mTOR in mice causes a very early (pre-implantation) lethality, while raptor null blastocysts stop growing. Rictor knockout embryos show a developmental delay and die about e10.5. These data attest to the central role that mTOR complexes play in cellular function and in development.

Rapamycin blocks the phosphorylation of certain substrates of mTORC1, such as p70 S6 kinase, but not all of them. In the

Figure 1 The composition of mTORC1 and mTORC2 and their best-characterized targets are depicted, together with an indication of the known mechanisms by which mTORC1 activity can be regulated. Also indicated are the main processes known to be controlled via these complexes.

short term, it does not affect the function of mTORC2, although it can do over longer time periods (24–72 h) in certain cell types.

Use of rapamycin has revealed that mTORC1 plays important and diverse cellular roles, as described in detail below. An early very important finding was that rapamycin blocks cell-cycle progression late in G1. It thus inhibits, for example, the activation of T lymphocytes, a feature that led to the application of rapamycin as an immunosuppressant to prevent (kidney) graft rejection.

Substrates for mTORCs

The S6 kinases were the first proteins discovered to be controlled by mTORC1 by virtue of the ability of rapamycin to inhibit their activation. S6Ks contain a TOS motif near their N-termini which allows them to interact with raptor and be recruited to mTORC1 to be phosphorylated by mTOR (Figure 2). The regulation of the S6 kinases shows the classical hallmarks of mTORC1 signaling, that is, they are activated by hormones and growth factors, and this activation (in many types of cells) is abrogated if cells are starved of amino acids and is also completely blocked by rapamycin.

The second well-understood group of mTORC1 targets are the eukaryotic initiation factor (eIF) 4E-binding proteins (4E-BPs; Figure 2). 4E-BPs bind to eIF4E, the translation initiation factor that interacts with the 5'-terminal 'cap' structure of eukaryotic mRNAs. When bound to a 4E-BP, eIF4E cannot interact with the scaffold protein eIF4G. mTORC1 directly

phosphorylates 4E-BP1, the best-understood 4E-BP, triggering its release from eIF4E, thereby activating eIF4E.

The functions of these mTORC1 substrates are discussed in detail below.

Other direct substrates for mTORC1 include the proline-rich Akt substrate of 40kDa, PRAS40, and ULK1, a protein kinase involved in controlling autophagy. PRAS40 has been described as both an upstream regulator and a downstream substrate of mTORC1; its full biological function remains obscure.

Regulation of mTOR Complexes

Signaling through mTORC1 is regulated by a wide variety of stimuli and conditions. It is activated by growth factors, mitogens and hormones, such as insulin. Key to the control of mTORC1 are Rheb, a small GTPase protein, and the proteins TSC1 and TSC2 (tuberous sclerosis 1 and 2). When bound to GTP, Rheb can stimulate mTORC1 signaling. TSC1/TSC2 act to hydrolyze Rheb-bound GTP to GDP, thus inactivating Rheb. TSC2 acts as a GTPase-activator protein (GAP) for Rheb. Agents that activate PI 3-kinase signaling switch on protein kinase B (also called Akt) which phosphorylates and apparently inactivates TSC2. This allows Rheb.GTP to build up, activating mTORC1. Stimuli that activate the classical mitogen-activated protein (MAP) kinase (extracellular ligand-regulated kinase (ERK)) pathway also appear to inactivate TSC2, activating mTORC1. As both the PI 3-kinase and ERK pathways contain proto-oncogenes (PI 3-k, Akt; Ras, Raf) and are inhibited by tumor suppressors (phosphatase and tensin homolog (PTEN);

Figure 2 (a) The best-known substrates for mTORC1 are shown schematically; TOS motifs are indicated. Phosphorylation events catalyzed by mTORC1 are shown in yellow and others in gray. The box shows the TOS motifs in proteins in known mTORC1 substrates; completely conserved residues present are underlined. (b) Cartoon of the layout of S6K isoforms, showing the shorter and longer splice variants of S6K1 and S6K2 including their nuclear localization sequences (NLS). Site shaded yellow is the one phosphorylated by mTORC1.

neurofibromin 1 (NF1)), mTORC1 signaling is very frequently activated in tumor cells. p53, another important tumor suppressor, also inhibits mTORC1 signaling.

mTORC1 is also sensitive to the energy and nutrient status of cells. Starvation of cells for amino acids results in profound inhibition of mTORC1 signaling, leucine generally being the most potent regulator of mTORC1. The mechanism by which amino acids activate mTORC1 remains to be fully identified; it appears to be independent of TSC1/TSC2 and to involve the Rag family of small GTPases.

Depleting cellular energy (ATP, adenosine triphosphate) (e.g., during hypoxia) also results in the impairment of mTORC1 signaling. This effect involves the AMP-activated protein kinase, a key sensor of cellular energy status, which can phosphorylate TSC2. The control of mTORC1 signaling by nutrients and energy status make excellent physiological sense given that mTORC1 promotes energy-requiring anabolic processes such as protein, ribosome, and lipid synthesis.

The control of mTORC2 is not understood; since mTORC1 phosphorylates proteins such as Akt and SGK1 which lie downstream of PI 3-kinase, it may be that mTORC2 is activated in some way by PI 3-kinase signaling, but there is currently no information on this.

Processes that are Controlled by mTORCs

Rapamycin has proved to be a very useful tool for identifying the cellular roles of mTORC1. It should be noted that recent work has demonstrated that not all mTORC1's functions are inhibited by this drug and further functions likely await identification. Because there is no specific inhibitor of mTORC2, far less is known about its cellular roles.

mTORC1

As judged by sensitivity to rapamycin, mTORC1 controls several diverse cell processes, including protein synthesis, ribosome biogenesis, the cell cycle, gene transcription, mitochondrial biogenesis, lipid metabolism, and autophagy. Of these, protein synthesis is the one whose control by mTORC1 is best understood. Regulation of the translation of specific mRNAs contributes to mTORC1's control of cell proliferation and cell survival.

Protein synthesis – initiation and elongation

As already mentioned, mTORC1 phosphorylates the translational repressor 4E-BP1, thus eliciting 4E-BP1's release from

Figure 3 mTORC1 controls several proteins involved in mRNA translation. S6ks phosphorylate IRS1 and inhibit its function (red cross). They may also control other processes. The links between mTORC1 and the control of other processes remain to be elucidated. Dotted arrows indicate indirect links.

eIF4E, allowing eIF4E to bind the scaffold protein eIF4G. eIF4G binds to several other proteins which are involved in the initiation of mRNA translation, that is, the binding of the small ribosome subunit to the mRNA and the identification of the translation start codon. 4E-BPs can thus hinder efficient initiation; this is probably especially important for mRNAs whose 5'-untranslated regions (5'-UTRs) contain secondary structure (stem loops). Such stem loops, between the 5'-cap and the start codon, can hinder the scanning ribosome's movement along the mRNA to find the start codon but can be unwound by eIF4A, an RNA helicase, which is recruited to mRNAs via its binding to eIF4G (Figure 3). Thus, 4E-BPs likely inhibit, in particular, the translation of specific, structured mRNAs. The subset of mRNAs whose translation is thought to be enhanced by mTORC1 via 4E-BP1/eIF4E includes several involved in driving cell-cycle progression (cyclin D1), angiogenesis (VEGF), and other proteins involved in the cell cycle and related events (such as c-myc).

As mentioned above, oncogenic signaling activates mTORC1, while certain tumor suppressors restrain it. A good deal of work has focused upon the importance of mTORC1 signaling in tumorigenesis; a key finding was that rapamycin strongly inhibits the proliferation of certain tumor cells and can inhibit tumor growth in animal models. Several lines of evidence point to a key role of eIF4E, downstream of mTORC1, in tumor biology. Indeed, increasing the levels of eIF4E can transform cells in culture and induce tumors *in vivo*. There is currently high interest in targeting mTORC1 signaling and eIF4E for cancer therapy.

S6 kinases

There are two S6K genes in mice and humans, S6K1 and S6K2, each of which gives rise to two mRNAs by alternative splicing and thus to two distinct proteins (which differ at their N-termini; Figure 2). The longer isoforms possess nuclear localization signals that target them constitutively

to the nucleus where they may regulate ribosome biogenesis and gene transcription.

Ribosomal protein S6, a component of the small ribosomal subunit, was the first substrate for the S6 kinases to be identified; however, the cellular role of S6 phosphorylation still remains unclear. It had been thought that phosphorylation of S6 promoted the translation of a set of mRNAs called 5'-TOP mRNAs (see below for further details). However, data from cells in which both the S6K1 and S6K2 genes have been deleted showed that control of the translation of 5'-TOP mRNAs does not require the S6 kinase. Subsequently, mice were created in which the 5 phosphorylation sites in S6 were mutated to residues which cannot be phosphorylated; data from cells from these mice showed that phosphorylation of S6 is also dispensable for control of 5'-TOP mRNAs.

Meantime, several other substrates for the S6 kinases have been identified, mainly proteins linked to mRNA translation. These include eIF4B and Pdcd4, which are respectively (Figure 3), activators and inhibitors of the helicase eIF4A. This likely assists the translation of mRNAs with structured 5'-UTRs. S6Ks also phosphorylate and inactivate eukaryotic elongation factor kinase (eEF2K) which itself phosphorylates and inhibits eEF2, which mediates the movement of the ribosome along the ribosome during the main, elongation, stage of polypeptide synthesis. Agents that activate protein synthesis elicit the dephosphorylation and activation of eEF2, helping to stimulate protein synthesis. This effect is blocked by rapamycin showing it is mediated by mTORC1. The phosphorylation of eEF2K by S6Ks provides one way that mTORC1 can switch off eEF2K (Figure 3). S6Ks provide a feedback loop from mTORC1 to inhibit signaling through insulin receptor substrate 1 (IRS1), which normally couples the insulin receptor to activation of PI 3-kinase signaling. S6ks can phosphorylate IRS1, thereby impairing its ability to couple the insulin receptor to PI 3-kinase, whereas S6K1 knock-out mice remain sensitive to insulin (Figure 3). Interestingly, wild-type mice fed a high-fat diet become obese and develop insulin resistance, whereas S6K1 knockout mice do not. This feedback loop may be important in obesity and type II diabetes in humans too.

Other substrates for the S6Ks have been reported, including SKAR, a protein involved in pre-mRNA splicing, and CREM, a transcription factor. The physiological role of S6K-mediated phosphorylation of these proteins is not fully understood.

Probably, the most striking phenotype observed in S6K knockout animals is growth restriction. This was first noted for fruit flies when the only S6K gene was inactivated, and later also reported for mice lacking S6K1. In flies, this seems to result from a defect in cell size (growth) rather than cell number (proliferation). The molecular basis of this effect is not yet understood.

Ribosome biogenesis

mTORC1 signaling positively regulates ribosome biogenesis, which is especially important for growing or dividing cells in order to maintain their capacity for protein synthesis. Ribosome biogenesis is a complicated process requiring the synthesis of four different ribosomal RNAs (rRNAs) and around 80 proteins. mTORC1 promotes the transcription of the rRNAs by RNA polymerases I and III, and the translation of the mRNAs that encode ribosomal proteins. The translation

of these mRNAs is controlled by a short pyrimidine-rich sequence at their 5'-end (5'-tract of pyrimidines; 5'-TOP). The 5'-TOP represses their translation in serum-starved cells, this inhibition being overcome by addition of serum in an mTORC1-dependent manner.

Cell cycle and cell survival – via mRNA translation?

As mTORC1 regulates protein synthesis, including the translation of specific mRNAs, it may influence many cellular processes (which are affected by the levels of proteins encoded by mRNAs whose translation is controlled, e.g., by eIF4E/4E-BP1). Two examples are the cell cycle and cell survival. As mentioned above, rapamycin blocks G1-S progression. This is, at least in part, due to the upregulation by mTORC1 of the translation of the mRNA for cyclin D1, which is required for progression into S-phase. Other components are likely also involved in the regulation by mTORC1 of this stage of the cell cycle. mTORC1 may also regulate G2-M progression by controlling the activity of cdc2-cyclin B.

The influence of mTORC1 signaling on cell survival appears to vary, depending on the cell line and perhaps the circumstances. The pro-survival effects of mTORC1 likely involve its ability to promote the translation of the mRNA for Mcl-1, an anti-apoptotic protein.

The abilities of mTORC1 signaling to promote cell proliferation (cell-cycle progression) and cell survival are likely to be of major importance in the roles of mTORC1 in cell transformation and oncogenesis (see below).

Autophagy

Autophagy is inhibited by signaling through mTORC1 but it is only recently that light has begun to be shed upon the mechanisms underlying this. In mammalian cells, mTOR interacts with a complex of proteins which includes a protein kinase termed ULK1 that plays an important role in the induction of autophagy. ULK1 is phosphorylated by mTORC1. It is also suggested that eEF2 kinase plays a role in inducing autophagy. Autophagy may play a role in tumor cells although it remains unclear whether it aids tumor survival or promotes tumor cell death. This likely depends on the tumor and its nutritional status, for example.

Gene transcription

In addition to its role in regulating rRNA synthesis by Pol I/III, mTORC1 can also regulate Pol II-mediated transcription of protein-coding genes. For example, mTOR is required to maintain the oxidative function of mitochondria. Conversely, rapamycin decreases the expression of a mitochondrial transcription factor, peroxisome proliferator-activated receptor- γ coactivator (PGC)-1 α , and of mRNAs for mitochondrial proteins involved in oxidative phosphorylation and the tricarboxylic acid cycle. mTORC1 interacts with the transcription factor YY1, which promotes mitochondrial gene expression. Positive control of mitochondrial function by mTORC1 makes sense given that mTORC1 promotes processes that need energy.

Lipid metabolism can also be controlled by mTORC1. For example, mTORC1 can activate a transcription factor called SREBP1 (sterol-response element-binding protein 1). SREBP1 activates genes for enzymes involved in fatty acid biosynthesis.

mTORC1 may also repress genes involved in lipid breakdown (lipolysis). Thus, mTORC1 signaling can promote the accumulation of lipids. This is likely important, among other things, for growing or proliferating cells which need to create additional membranes.

Protein phosphatases

Signaling through mTORC1 may regulate the activity of protein phosphatases which would contribute to control of the states of phosphorylation of specific proteins in the cell. It is well established that yeast TORC1 controls protein phosphatases PP2, PP4, and PP6. However, much less is currently known about the control of protein phosphatases by mTORC1.

mTORC2

In contrast to the rather extensive knowledge about the functions of mTORC1 and its substrates, much less is known about mTORC2. This largely reflects the absence of a specific inhibitor of mTORC2 with which to define mTORC2's functions analogous to rapamycin for mTORC1. The only substrates for mTORC2 that have so far been identified are members of the AGC group of serine/threonine kinases. AGC family kinases, which also include the S6 kinases, are activated by phosphorylation in their activation loop (within the kinase domain) and at a second site located in a hydrophobic motif. mTORC1 and mTORC2 phosphorylate, respectively, the hydrophobic sites in the S6Ks and in PKB (Akt) and SGK1 (the serum-and glucocorticoid-induced kinase).

The significance of phosphorylation of the hydrophobic site in Akt for its activity against different substrates may vary; its importance for SGK activity seems more clear-cut. mTORC2 may also phosphorylate some other AGC family kinases, for example, members of the protein kinase C (PKC) group.

Like its yeast counterpart, mTORC2 also controls the actin cytoskeleton, perhaps via Rho GTPases.

mTOR in Human Disease

There is currently intense interest in the potential value of inhibiting mTOR signaling to treat human diseases and other conditions. These include sirolimus, ridaforolimus, temsirolimus, and everolimus. As discussed above, rapamycin has been used since the 1990s to tackle kidney graft rejection. Rapamycin, delivered via metal stents, is frequently used to treat restenosis, a complication of cardiac surgery caused by proliferation of smooth muscle cells. Rapamycin itself is a poor drug on account of its pharmacokinetic properties, leading the development of modified versions of rapamycin known as 'rapalogs'. Most recently, specific inhibitors of the kinase activity of mTOR have been developed; these inhibit mTORC1 and mTORC2, and have revealed that not all the functions of mTORC1 are inhibited by rapamycin.

A major area of therapeutic interest is cancer, based on observations such as rapamycin's potent ability to inhibit tumor cell proliferation *in vitro* or tumor growth in animals *in vivo*. A good deal of effort concerns the role of mTORC1-regulated translation in cell proliferation and survival, with eIF4E being considered a potentially valuable therapeutic

target. Autophagy may also be a relevant target for anti-tumor therapies linked to the inhibition of mTOR signaling. Other situations where inhibiting mTOR may be of therapeutic value are neurodegenerative conditions such as Huntington's and Parkinson's diseases; tuberous sclerosis, where initial data indicate benefit even in terms of patients' cognitive functions; and possibly type II diabetes and related disorders.

Concluding Remarks

Recent studies have provided a wealth of information about the cellular roles of mTOR and especially mTORC1 revealing the central role this pathway plays in cell physiology. These discoveries raise further important questions, for example, about which molecules provide the links between mTORC1 and the control of cellular processes such as ribosome production and gene transcription. The answers will be valuable for understanding both the normal roles of mTOR and how its defective control contributes to human disease.

Mucin Family of Glycoproteins

R B Brown and M A Hollingsworth, University of Nebraska Medical Center, Omaha, NE, USA

Published by Elsevier Inc.

Glossary

Glycoproteins Proteins with oligosaccharide (carbohydrate) chains covalently attached to their polypeptide backbones.

Mucus Viscous aqueous secretions produced by epithelial cells mainly composed by mucins, ions, and water.

N- and O-linked oligosaccharides Oligosaccharide chains linked to serine or threonine and asparagine residues in glycoproteins, respectively.

Peptide motif Peptide sequence that has a critical function during the biosynthesis, processing, or assembly of a protein

(e.g., the CXCC motif is required for dimerization via the mucin CK-like domains), or for the role of a protein.

Protein domain A region in the polypeptide chain of a protein that has a specific function (e.g., the CK-like domain in gel-forming mucins is a dimerization domain).

Secretory pathway Biosynthetic pathway taken by mucins and other glycoproteins that involves different organelles, for example, endoplasmic reticulum and Golgi complex, and many consecutive co-/posttranslational modifications, including folding, N-/O-glycosylation, disulfide bond formation, sulfation, etc.

Mucin Glycoproteins

Mucins are a diverse group of high-molecular-weight glycoproteins expressed by secretory epithelia and other cell types. As components of the cell surface and of secretions, mucins form high-order structures through oligomerization and association with other molecules. Molecular features of mucins create specialized biochemical microenvironments at cellular surfaces and interfaces, specific to each cell type, that enable specific functions associated with those cell types. Many of the molecular features of mucins that are important to their function result from posttranslational processing that creates higher-order structures. For example, most mucins are comprised of greater than 90% carbohydrate that results from posttranslational modification by dozens of glycosyltransferases. Higher-order structures of mucins are created through oligomerization that is mediated by formation of disulfide bonds and other covalent and noncovalent interactions.

One biochemical feature that defines mucins is the presence of tandemly repeated domains rich in serine, threonine, and proline, that are heavily O-glycosylated (mucin-type O-glycosylation of serine and threonine by *N*-acetyl-galactosamine that is extended with linear and branched structures attached by hundreds of different glycosyltransferases). Tandem repeat domains are found in all mucins, but they are highly variable in length, number of repeats, and specific sequence. One function of the repeat domain is to create multivalent structures that serve to create locally high concentrations of specific molecular structures (protein, carbohydrate, or a combination of these, which is termed 'glycopeptide'). These structures function in different ways by serving as ligands for other molecules that are intercalated into a mucin layer or by creating a dense hygroscopic and possibly charged molecular environment that may serve as a barrier or to selectively facilitate transport of molecules across a protective barrier at epithelial surfaces.

Glycosylation

Glycosylation is a posttranslational modification of proteins processed in the secretion pathway of eukaryotes. The reaction is catalyzed by hundreds of glycosyltransferases, each catalyzing a specific glycosidic linkage.

Mucin-Type O-Glycosylation

Mucins are structurally diverse and can range in size from a few kDa to 50 MDa. Most mucins contain a tandem repeat domain that is comprised of conserved sequences of amino acids repeated many times. Some tandem repeats exhibit a high degree of polymorphism in length and/or sequence. The tandem repeat domain is often rich in Pro, and the hydroxy-amino acids Ser and Thr that are modified initially by covalent O-linked attachment of an *N*-acetyl-galactosamine followed by addition of a diverse array of oligosaccharide chains that include fucose, galactose, *N*-acetylneuraminic acid (sialic acid), *N*-acetylglucosamine, and *N*-acetylgalactosamine (GalNAc). O-linked oligosaccharides in the mucin domain comprise 50–90% of the physical mass of the protein and are largely responsible for the structural and biological properties of these glycoproteins, including protease resistance, pathogen sequestration, and binding of ions and water, which enables a high degree of hydration and affects their visco-elastic properties. Several saccharides present in O-linked oligosaccharide chains can be sulfated, including galactose, *N*-acetyl-galactosamine, and *N*-acetyl-glucosamine. These sulfated saccharides protect the oligosaccharide chains from bacterial glycosidases and establish a significant negative charge that may establish ionic repulsive forces between carbohydrate chains, or adhesive properties to positively charged molecules. The repulsive forces stiffen and elongate the protein while preventing rotation around the polypeptide backbone, permitting the molecules to occupy a large volume of the luminal space. The relative abundance of

Figure 1 The VNTR consists of repetitive tandem repeats. The theme of a repeat is common to all members of the mucin family but there is significant diversity in sequence and length. This region may exist as a continuous, repeating domain, or the secreted mucins MUC2, MUC5AC, and MUC5B contain cysteine-rich CS domains interspersed throughout the VNTR. The transmembrane and cytoplasmic tail of membrane-bound mucins is found at the far C-terminus. The SEA domain depicted in red is present in all membrane-bound mucins, except MUC4. The posttranslational autoproteolytic cleavage event of these membrane-bound proteins yields two functional protein fragments that remain tightly associated through noncovalent bonds. The CS-Cys domains of MUC16 contributes to formation of tight higher-order oligomerized structures. These cysteine-rich regions are most typically found in the CK, D, and CS domains of the secreted mucins. The oligomerization of these proteins into high-order structures, with high degrees of hydration, give the mucus gel adhesive and viscoelastic properties.

sulfated saccharides available for O-glycan synthesis varies depending on the physiological state of the cell or tissue type. Differences in number and type of O-glycans added to mucins create a diverse range of mucin isoforms in the body.

N-Glycosylation

N-linked glycosylation of mucins typically occurs in cysteine-rich regions outside of the mucin domain, and at a minimum contributes to proper protein folding, and transport to the Golgi. N-linked oligosaccharides are attached via a GlcNAc linkage to the side chain nitrogen of Asn in the consensus sequence NXT/S ($X \neq P$) known as the 'glycosylation sequon'. The precursor branched carbohydrate chain contains three glucose, nine mannose, and two N-acetylglucosamine sugars that are attached by oligosaccharyltransferase to Asn. The removal of the three glucose sugars signals completion of N-linked glycosylation and transport to the Golgi where mannose is removed yielding a carbohydrate chain containing five-nine mannose sugars. Further removal of mannose residues can lead to the core structure containing three mannose and two N-acetylglucosamine residues, which may then be elongated with a variety of different monosaccharides including galactose, N-acetylglucosamine, N-acetylgalactosamine, fucose, and sialic acid, many of which can also exist in sulfated form.

Mucin Protein Family Members

To date there are 17 proteins classified as mucins. There are 10 genes that encode cell-tethered mucins (MUC1, MUC3A, MUC3B, MUC4, MUC12, MUC13, MUC15, MUC16, MUC17, and MUC20). The other seven genes encode for secreted mucins, classified as either secreted polymeric (MUC2, MUC5AC, MUC5B, MUC6, and MUC19) or secreted nonpolymeric

(MUC7 and MUC8). There is a large and diverse group of cellular proteins that contain a mucin tandem repeat domain in their structure; however, some of these proteins have distinct, well-characterized biological functions that do not classify them as typical mucins.

Membrane or Tethered Mucins

The tethered mucins are single-pass integral transmembrane proteins that contain a cytoplasmic tail that associates with cytoskeletal elements, cytosolic adapter proteins, and in some cases facilitates signal transduction. Some mucins exhibit the posttranslational autoproteolytic cleavage event that creates two tightly associated subunits. For example, an autoproteolytic cleavage event occurs at G↓SVVV in the SEA domain of MUC1. Other mucins contain these domains but whether the autoproteolytic cleavage occurs is not yet established. MUC4 does not contain a SEA domain but undergoes autoproteolytic cleavage at a G↓DPH. The large N-terminal subunit containing the tandem repeat is extracellular, while a smaller C-terminal subunit contains short extracellular, transmembrane, and cytoplasmic tail domains. Following autoproteolysis, the two subunits of membrane-associated mucins remain associated by noncovalent interactions. Other biochemical events result in shedding of membrane-associated mucins from the cell surfaces. For example, the amino-terminal subunit of MUC1 can be shed into the extracellular space when cleaved by the proteases such as TACE/ADAM17 and ADAM9. Recent characterization of MUC1 and MUC4 splice variants that lack transmembrane domains provides examples of soluble isoforms that lack the transmembrane domain and are directly secreted from the cell. The lactating mammary gland produces high levels of soluble MUC1 and MUC4 that has been found in breast milk. The ciliated cells comprising the airway epithelium also synthesize soluble forms of MUC1, MUC4, and MUC16 that contributes to 10% of the mucin raft.

Major Domains in Membrane Mucins

Epidermal Growth Factor-Like Domains

The epidermal growth factor (EGF)-like domain is a stretch of 30–45 amino acids containing six conserved cysteine residues, three of which form evenly spaced disulfide bonds that are similar among other EGF-like domain containing proteins. The domain is named due to similarity to the growth factor EGF. The membrane-bound mucins MUC3A, MUC3B, MUC4, MUC12, MUC13, and MUC17 contain these domains between the variable number tandem repeat (VNTR) and transmembrane domain. The functions of these domains are not fully understood, but they may contribute to ligand–receptor interactions between mucins and receptors. For example, there is evidence that MUC4 binds to the EGF-like receptor ERB-B2.

SEA-Like Domains

The SEA-like domain is a stretch of 85–110 amino acids located between the tandem repeat and the transmembrane domain of MUC1, MUC3A, MUC3B, MUC12, MUC13, and MUC17. SEA-like domain contains the GSVVV motif that contributes to autoproteolytic cleavage of the tethered mucins.

Other Domains

MUC4 contains an other protein (AMOP), *nidogen* (NIDO)-like, and adhesion-associated domains. The presence of similar domains on adhesion proteins suggests that they likely serve a function in cellular adhesion.

The Transmembrane Domain

Membrane-associated mucins are anchored in the membrane by a type I transmembrane domain, comprised of 20–35 hydrophobic amino acids near the C-terminus that transverses the membrane once, anchoring the protein to the cell.

The Cytoplasmic Domain

Many membrane-associated mucins contain a short stretch of <100 amino acids at the C-terminus, known as the ‘cytoplasmic domain’, or ‘cytoplasmic tail’. While each cytoplasmic tail varies in length and composition, individual mucin sequences are usually highly conserved among species, suggesting that they mediate fundamental biological processes. One major function of this domain is to engage in signal transduction within the cell in response to alterations in stimuli or the condition of the external environment or cell surface. The best studied of these is MUC1, which can be phosphorylated by a number of receptor tyrosine kinases at the cell surface. The phosphorylation of MUC1 by Met, epidermal growth factor receptor, and other kinases, has been shown to initiate MUC1 internalization and transport into the nucleus where it binds transcription factors at distinct and multiple promoters to control patterns of gene expression. While most studies have focused on Tyr phosphorylation, it is also known that a majority of the 21 Ser, Thr, and Tyr in the MUC1 cytoplasmic tail can be phosphorylated in complex patterns that dictate subsequent

binding to signaling proteins or transcription factors. Thus, signaling through membrane-associated mucins invokes alteration of transcriptional programs in response to external or cell surface stimuli.

Other examples include recent studies into MUC1 signaling that have shown that flagella present in *Pseudomonas aeruginosa* can bind oligosaccharides within the VNTR and initiate a signaling cascade that ultimately leads to ERK1/2 phosphorylation and activation. The pathway is not understood but involves a phosphorylation event that recruits Grb2-Sos-Ras-MEK1/2-ERK1/2.

AP-2 Domain

Some membrane mucins such as MUC1 are internalized into the cell through the formation of clathrin-coated pits via endocytosis. The cytoplasmic tail of MUC1 contains the AP-2 binding motif (YXXO) just C-terminal to the transmembrane domain. The binding of AP-2 to MUC1 is responsible for the recruitment of clathrin and formation of endocytic vesicles.

Secreted Mucins

Secreted mucins are large glycoproteins that lack a transmembrane domain and are usually produced by specialized mucus-producing cells (goblet cells or other specialized cell types in submucosal glands). Secreted mucins have gel-forming properties that are the result of extensive intermolecular cross-linking through disulfide and other covalent and noncovalent molecular bonds. These mucins are major components of the thin or thick mucus that coats many of the epithelial surfaces of the eyes, respiratory tract, gastrointestinal tract, urinary tract, breast, and reproductive tracts. Mucus gels have specialized adhesive and viscoelastic properties that are specific for the biological needs of the different epithelial surfaces on which they are expressed. Different combinations of MUC2, MUC6, MUC5AC, and/or MUC5B together constitute 90% of the mucin in mucus gels. These proteins are packaged and stored in large secretory vesicles known as ‘mucin granules’ that are secreted via exocytosis. The regulated secretion is activated by differentiation, cytokines, chemokines, neurotransmitters, and/or proteases.

Protein Domains in Secreted Mucins

D-Domains

D-Domains are named for their similarity to the D or dimerization domains of von Willebrand factor. The secreted mucins contain three homologous N-terminal D-domains (D1, D2, and D3) and, all but MUC6, a fourth domain, D4, at the C-terminus. A partial D-domain, D', is between D2 and D3 in all secreted mucins. The D-like domain is a cysteine-rich stretch of 325–400 amino acids that contains several conserved N-glycosylation acceptor motifs. The functions of D-like domains include the ability to mediate dimerization, trimerization, and oligomerization of secreted mucins and they may serve to cross-link mucins to other D-like domain containing glycoproteins. There is also evidence that these domains bind other smaller proteins found in secreted mucus, including

trefoil factors, cytokines, chemokines, and other secreted components.

Cystine Knot Domains

The cystine knot (CK)-like domain is a cysteine-rich domain at the C-terminus of secreted mucins, consisting of 90–100 amino acid residues. The domain is extensively N-glycosylated and is believed to contribute to mucin oligomerization through disulfide linkages.

Cys Subdomain Domains

The Cys subdomain (CS) domain is comprised of a cysteine-rich stretch of 100 amino acids. The domain is distributed throughout the VNTR of MUC2, MUC5AC, and MUC5B, and contains a C-mannosylation acceptor motif (WXXW), that is C-mannosylated on Trp, via covalent C–C link attachment of an α -mannopyranosyl residue to the indole C2 carbon of Trp. This form of glycosylation is fundamentally different from N- and O-linked glycosylation and has not been well studied.

Roles in Disease

Pulmonary Disorders

The heavily glycosylated tandem repeat of mucins is key to providing protection of epithelial cells in airways. The mucus layer in the airways requires maintenance of a protected epithelial surface at the air–water interface, laden with bacteria and physical debris, that must also undertake exchange of oxygen and carbon dioxide. The sialylated and sulfated O-glycans offer high degrees of hydration, lining the epithelium, such as the airways, with a layer of mucus. The diversity in glycosylation is likely to allow for specific binding to most, if not all, pathogens that come in contact with airway surfaces. The peristaltic motion provided by cilia move the pathogens attached to secreted mucins for secretion out of the body; however, these hypersecretory responses are also the major contributing factor to the three chronic airway diseases asthma, chronic obstructive pulmonary disorder, and cystic fibrosis. In some circumstances, mucus has been observed to be tethered to the epithelium. These thick layers of mucus typically have altered transport properties and can build in the airways, providing a warm moist environment where bacteria can flourish. These pathogens often activate the innate and adaptive immune response causing inflammation of the airway.

Gastrointestinal Disorders

Mucins are critical components of every epithelial surface of the gastrointestinal tract. The molecular features of the mucins produced by normal epithelial surfaces are specific to the biological requirements of the different organ sites. For example, the needs of the mouth and esophagus require lubrication and protection of surfaces associated with chewing and swallowing of relatively large items of food mixed with liquid. The stomach is lined by a mucus layer that separates the epithelial surface from masticated food in acid at pH 2. Different sections of the intestines deal with digestion and absorption of complex

foods, exchange of waste products, and peristalsis. Consequently, there are different mucin core proteins that are glycosylated in different ways at these different locations. MUC5b and MUC7, produced by the salivary glands, protect the oral cavity and esophagus. The mucus glands of the stomach produce MUC5ac, MUC6, and MUC1. The lower GI tract produces MUC2 and MUC5ac. Disruptions in the production of specific mucin proteins at these sites alters the surface properties of the gastrointestinal epithelia and can lead to alterations in the colonization of these areas by microbial flora, with a change from probiotic bacteria to pathogenic strains. This can also affect the protection of the surface of the epithelia and lead to inflammatory conditions of the intestine and secondary effects including cancer.

Ocular Surfaces

Mucins are an important component of the tear film, providing protection and lubrication of the ocular surface. MUC1, MUC4, and MUC16 are associated with tears, and both MUC2 and MUC5ac have been found in ocular secretions. Differences in the production and glycosylation of these mucins have been reported in conditions of dry eye syndrome and Sjogrens syndrome.

Cancer

Most human adenocarcinomas express mucins, in part, because they arise from the tissues and cell types that normally express mucins. Human tumors typically express molecular forms of mucins that are distinct from the corresponding normal cell type in both types of proteins expressed and in their glycosylation and other posttranslational modification. Studies of human tumors have shown overexpression of MUC1, MUC4, and MUC16 in a variety of cancers. MUC1 overexpression has been observed in greater than 90% of epithelial cancers, including lung, colon, ovarian, breast, and pancreas. For example, extensive studies of the pancreas show low-level expression of MUC1 and little to no MUC4 in normal epithelial cells. MUC4 becomes expressed in precursor lesions known as ‘pancreatic intraductal neoplasms’, or ‘PanINs’. Following malignant transformation, there are significantly higher levels of MUC1 and MUC4 that further increases with tumor progression. The increased level of MUC1 in some breast cancers correlates with poor prognosis and so is used as a prognostic serum marker known as ‘CA15-3’. Similarly, MUC16 (CA125) has longstanding use as a serum marker for ovarian cancer, and, more recently, MUC4 is being studied as a potential marker of aggressive pancreatic cancers.

There are other functional differences observed with tumor progression. MUC1 has been well studied for its ability to act as a cell-signaling protein through the cytoplasmic tail. On normal epithelial cells, MUC1 is found almost exclusively on the apical membrane, whereas following transformation cellular polarity is lost and MUC1 is expressed throughout the plasma membrane. The interaction of MUC1 and growth factor receptors alters cellular signaling pathways and typically leads to high levels of the MUC1 cytoplasmic tail throughout the cytoplasm and nucleus. The VNTR of the extracellular N-terminus of MUC1 undergoes significant alterations in its pattern of

glycosylation. The tumor-derived MUC1 is often aberrantly glycosylated, where the carbohydrate chains tend to be shorter and contain moieties not present on normal MUC1.

The exact roles that mucins play in cancer have not been completely elucidated. There have been many earlier reports that mucins contribute to tumor progression and metastasis through actions at the cell surface that involve the adhesive and anti-adhesive properties of the tandem repeat moiety. The uniform expression of mucin over the entire surface of a depolarized tumor cell would allow for a reconfiguration of the adhesive/antiadhesive properties, allowing the tumor cell flexibility during the process of invasion and metastasis. The steric hindrance provided by these structures could provide a protective boundary from attack by immune cells. The propensity for mucins to interact with adhesion molecules may also play an important role for invasion and metastasis; such is the case with MUC1 binding the endothelial protein ICAM-1, which is expected to play a critical role in invasion. Signal transduction by membrane-associated mucins is undoubtedly important to malignant progression of tumors to a metastatic condition. For example, specific phosphorylated forms of the cytoplasmic tail of MUC1 associate with transcription factors that are involved in cancer progression, such as p53. MUC1/p53 complexes are localized to promoter regions of groups of genes whose expression is altered as a consequence of signaling through the mucin cytoplasmic tail. This results in alterations in transcriptional programs in the cell that affect cell division, motility, apoptosis, differentiation status, or secretion of cytokines and growth factors. It is believed that tumors have appropriated these normal functions in order to survive under different conditions encountered during the phases of uncontrolled growth and metastasis.

Glossary

Embryo implantation The process by which the mammalian embryo binds to and implants into the uterine wall.

MUC1 The first transmembrane mucin glycoprotein to be completely molecularly cloned.

Mucin Any member of a class of glycoproteins that contain a large number of oligosaccharides linked

through the hydroxyl groups of serine or threonine via *N*-acetylgalactosamine.

Uterus The upper portion of the female reproductive tract into which the mammalian embryo normally implants and in which the fetus develops.

Mucin glycoproteins are defined as proteins heavily substituted with oligosaccharides in O-glycosidic linkage between *N*-acetylgalactosamine and S/T residues. Carbohydrates can account for 50–90% of the mucin molecular weight and greatly influence the physical properties of these molecules. Mucins are also predominant constituents of the apical surfaces of reproductive tract epithelia. In many species, uterine mucin expression changes dynamically during the reproductive cycle and in preparation for embryo attachment. This article summarizes current knowledge of factors controlling the expression and function of uterine mucins with particular emphasis on MUC1 and the process of embryo implantation.

The Implantation Process

The process of embryo implantation into the uterine wall involves complex interactions between embryonic- and uterine-derived factors. These factors include secreted signals as well as cell-surface recognition events. With regard to the latter, a number of cell-surface components have the ability to support embryo attachment and are located at sites of embryo uterine attachment. These include integrins, proteoglycans, and cadherins. The failure of gene knockouts of any of these receptors to prevent the initial events in implantation indicates that there is considerable redundancy in function. This is consistent with *in vitro* studies demonstrating the ability of embryos to attach to a wide variety of cell types and substrates via different cell-surface receptor systems as well as the ability of trophoblast to modulate their cell-surface expression of such receptors in response to the extracellular matrix they encounter (Figure 1).

In spite of the highly invasive nature of blastocysts and trophoblast, the uterus displays the remarkable ability to limit both embryo and tumor cell attachment and invasion. Only during a well-defined window in time does the uterus permit attachment to and penetration of the endometrium. This control appears to be primarily exerted at the first point of encounter, namely the apical surface of the luminal epithelium. In response to ovarian steroid influences, the uterus develops through a series of stages that may be defined as

prereceptive, receptive, and postreceptive with regard to the ability to support embryo attachment. The end of the ovarian cycle is marked by a fall in steroid hormone levels and resetting of the uterine clock to begin another cycle of receptivity. In menstruating species, the endometrium is largely sloughed and new tissue is formed; however, in most species, menstruation does not occur and the endometrium is restructured via processes involving controlled apoptosis and cell proliferation as well as extracellular matrix remodeling. If implantation occurs, steroid hormone levels are maintained and the endometrium not only remains, but also differentiates further in many species in a process called the 'decidual response'.

During the receptive phase, the uterine epithelium also displays remodeling, which is evident by electron microscopy as well as by light microscopy if staining for specific markers is used. While there are many species-specific variations on the theme, there are features of this process that are well conserved across species. These include retraction of apical microvilli and reorganization of the cortical actin filaments, the transient appearance of large membrane protrusions (pinopods or uterodomes), and alterations in the apical glycocalyx. Much of the apical glycocalyx is composed of large, heavily glycosylated glycoproteins identified as mucins. This article briefly summarizes our current knowledge of the function and expression of mucins in the context of the embryo implantation process.

Mucins

Functions

As a general principle, mucins heavily coat the luminal surfaces of epithelia where they provide the first line of defense against infectious agents as well as degradative enzymes. Consistent with this role, mucin glycoproteins are highly resistant to proteolytic attack and require the actions of multiple glycosidases to remove their constituent carbohydrates. While mucins provide a barrier to infection, it is clear that many bacteria and viruses bind well to mucins. Thus, the concept emerges that these molecules serve as traps for the infectious agents that interact with them before they can establish contact with the plasma membrane of the host epithelium. A number

Figure 1 Mucin dynamics during embryo implantation. Uterine epithelial cells produce mucins, including transmembrane mucins such as MUC1 (represented by the squiggly lines in the figure). In general, these mucins are believed to be a barrier to embryo attachment that must be removed to create access to the apical surface of the uterine epithelium. In some cases, mucin gene expression can be regulated by ovarian steroids, estrogen (E_2) and progesterone (P_4) that may act through their nuclear receptors (ER and PR) directly or indirectly on the MUC1 promoter. Cytokines, produced by neighboring stromal cells or the embryo, which bind to cell-surface receptors (Rec) on uterine epithelia can also regulate MUC1 gene expression via NF κ B and STAT binding and transcriptional co-regulators. These same elements also may be downstream of steroid hormone actions. Cytokines can also trigger loss of mucin protein by causing increased expression or conversion of latent (Inact) cell-surface proteases or sheddases to active forms (Act) that catalyze mucin ectodomain release. Mucins may also be removed by endocytosis and intracellular degradation pathways.

of mucins occur as transmembrane proteins (Table 1). MUC1 is an example of a transmembrane mucin glycoprotein and experiments with MUC1-null mice demonstrate that these animals are much more prone to bacterial infection and inflammation than their wild-type counterparts. Thus, a paradox arises over how a glycoprotein that can promote attachment of an infectious agent simultaneously serves to protect against the microbe. As discussed subsequently, the host may be able to recognize attachment and shed the ectodomains of transmembrane mucins in response. This process then would convert the shed mucins into a soluble mucin trap, removing the potential pathogen from the cell surface.

In the context of embryo implantation, mucins also appear to be anti-adhesive. Polarized uterine epithelia of rodents are constitutively nonreceptive *in vitro* and abundantly express mucins. Selective, enzymatic removal of mucins or genetic ablation of Muc1 converts these cells into a functionally receptive state. Early pregnancy studies in the human MUC1 mouse model indicate a reduced, yet persistent level of human MUC1 expression in the peri-implantation stages. Moreover, transfection and overexpression of MUC1 into cells that normally adhere well to blastocysts markedly reduce their adhesive activity. In contrast, under some conditions, mucins can carry selectin ligands and, thereby, potentially support cell attachment. Recent studies indicate that this occurs at the fetal-maternal interface and may contribute to aspects of trophoblast binding.

In addition to being abundantly expressed at the apical surface of uterine epithelia, mucins are physically very large with individual molecules being hundreds of nanometers in length. By contrast, typical cell-surface receptors extend 10–30 nm from the cell surface. Due to their heavily glycosylated nature, individual mucins have large hydration spheres. In addition, mucins often form complex aggregates or gels. Consequently, the mucin coat presents a large, formidable matrix that must be somehow traversed or removed in order for molecules or cells to establish contact with the plasma membrane. The size of the ectodomains is an important determinant of transmembrane mucin function as an anti-adhesive molecule. Truncation mutations of the ectodomains of both MUC1 and MUC4 demonstrate that these mucins must extend more than 50 nm from the cell surface to be effective. This would extend well beyond the distance spanned by most cell-surface receptors.

Other interesting functions associated with mucins include immunosuppression and association with intracellular signal-transducing molecules. In the former case, the mechanism of action is not clear, although effects on several cell types involved in cell-mediated immunity have been reported. In the case of signal transduction, MUC1 has been shown to be associated with β -catenin, Grb2, epidermal growth factor (EGF) receptor, and participates in numerous other intracellular signal transduction pathways. Furthermore, tyrosine phosphorylation of the cytoplasmic tail is stimulated when ligand is added to cells expressing a fusion protein consisting of a ligand binding extracellular domain and the MUC1 cytoplasmic tail. The physiological significance of these interactions has not been demonstrated, although EGF treatment appears to both increase MUC1 association with EGF receptor and activated EGF receptor can tyrosine-phosphorylate the cytoplasmic tail of MUC1, an event suggested to increase MUC1: β -catenin association. Since most of these interactions have only been observed in cancer cells or cancer cell lines, it is possible that these associations only occur in contexts where MUC1 is overexpressed or aberrantly localized. An exception is the association with epidermal growth factor receptor (ErbB) family receptors, which have been shown in both normal and cancer cells.

Expression and Transcriptional Control

To date, 21 mammalian mucin genes have been identified. The predicted protein structures indicate that the protein cores fall into two classes, soluble and transmembrane. As discussed later, even transmembrane mucins may be shed from the cell surface and so may contribute to the pool of soluble mucins. As a general principle, much of the core protein structure is composed of tandemly repeated sequences rich in serine, threonine, and proline, thereby capable of carrying many O-linked oligosaccharide chains. Secreted mucins also usually contain multiple cysteine-rich regions that participate in disulfide bond formation and the assembly of mucin gels. A hallmark feature is the presence of a large number of O-linked oligosaccharides that can constitute 50–90% of the molecular weight of the glycoprotein. A number of mucin oligosaccharide structures have been determined and considerable information on the glycosyltransferases that assemble these structures is available. The oligosaccharides are branched, can be reasonably complex,

and carry a net negative charge due to the presence of sialic acid and/or sulfate residues.

The structures of reproductive tract mucin oligosaccharides change during the cycle under the influence of ovarian steroids. Consistent with this are studies showing that glycosyltransferase activities in endometrium also change in parallel. Expression of messenger RNA (mRNA) encoding certain mucin core proteins also changes during the cycle; however, only changes in the expression of MUC1 have been extensively characterized. MUC4 and MUC16 are other mucins that have been studied in any detail, in this regard (see Table 1). In rodents, estrogen strongly stimulates Muc1 expression. Progesterone alone has no effect on Muc1 expression, but antagonizes this estrogen action. Both the actions of estrogen and progesterone on Muc1 expression are mediated by their corresponding nuclear receptors. The murine Muc1 promoter contains a number of sequences that are good candidates for estrogen receptor as well as for progesterone receptor (PR)-binding sites; however, none of these sites appears to be functional with regard to estrogen receptor- α or - β . Thus, estrogen actions are likely to be indirect and may be mediated in a paracrine fashion by estrogen-regulated growth factors or cytokines. Consistent with this is the conservation of a functional STAT and nuclear factor kappa B (NF κ B)-binding site in the mouse and human MUC1 promoter. Proinflammatory cytokines strongly stimulate MUC1 expression in various cellular contexts. In human mammary and uterine epithelial cells, STATs stimulate MUC1 expression via the STAT-binding site. Synergy with other cytokines has been observed, notably tumor necrosis factor- α (TNF- α). In this case, cooperativity with p65 and a corresponding NF κ B-

binding site appear to further enhance MUC1 transcription. It is noteworthy that these cytokines are highly expressed in the mouse uterus at times when MUC1 levels are high as well, for example, estrus and day 1–2 *post coitum*, most likely in response to the microbial challenge associated with coitus. Thus, this response may help protect the reproductive tract from infections that would trigger implantation failure or abortion.

Hormonal regulation of reproductive tract mucin expression is observed in other species as well, although in many cases progesterone stimulates mucin expression. PR regulates MUC1 gene expression in a PR isoform-specific fashion with PRB being stimulatory and PRA antagonizing PRB actions in both, human uterine epithelial cell line and mouse uterine epithelia *in vivo*. The progesterone responsiveness is mapped to a region and not specific to a PR-binding site in the human MUC1 promoter. Progesterone and changes in the levels of proinflammatory cytokines contribute toward a successful implantation. Progesterone and cytokines, in concert with each other, control MUC1 gene expression, regulated by transcriptional cofactors (Figure 2). Steroid hormone receptor coregulators regulate gene transcription by bridging the transcriptional machinery. Furthermore, steroid regulated co-activators (SRCs) are expressed in a cyclical manner in the human endometrium. SRC-1, SRC-3, and nuclear receptor corepressor (NCoR) bind to the MUC1 promoter and regulate MUC1 gene expression. Other cofactors such as p300 are also important in the stimulation of MUC1 gene expression.

In rats, MUC4 expression is also strongly regulated by progesterone and estrogen. In addition, transforming growth factor beta (TGF- β) downregulates MUC4 expression in both

Figure 2 Proposed model for transcriptional regulation of MUC1. This illustration depicts three proposed pathways for regulation of MUC1 expression. Pathway (1) illustrates PR isoforms interacting directly with NF- κ B and STAT1 α to regulate MUC1 expression; (2) illustrates MUC1 expression by interaction between NF- κ B, STAT1 α , nuclear steroid receptor coactivators (SRC), and PR isoforms; pathway (3) illustrates antagonism by PIAS family members and PPAR γ , possibly by recruiting corepressors (NCoR and SMRT). Both PIAS family members and PPAR γ repress MUC1 expression, possibly by altering the transcriptional initiation complex instead of binding to MUC1 promoter directly. Rosiglitazone activates PPAR γ and antagonizes P-stimulated MUC1 expression by interfering with PR-dependent gene activation by as-yet undefined mechanisms and/or causing a decrease in progesterone receptor (PR) protein levels. PIAS represses both basal and P-stimulated MUC1 expression, possibly by reducing the recruitment of a cofactor, NCoR, that appears to have a nonconventional association with the activated, rather than repressed, state of the MUC1 promoter. Reproduced from Carson DD, Dharmaraj N, and Wang P (2008) Transcriptional control of the expression of MUC1. *Expert Review of Endocrinology and Metabolism* 3: 463–471, with permission.

mammary and uterine epithelium. Another transmembrane mucin, MUC16, regulated by steroid hormones, is reduced during receptive phase in humans. Few negatively acting factors on MUC1 expression have been recently reported. Members of the PIAS family were found to inhibit both progesterone- and cytokine-stimulated MUC1 expression. A peroxisome proliferator-activated receptor gamma (PPAR γ) agonist, rosiglitazone, antagonizes progesterone-stimulated MUC1 expression, in contrast to the murine Muc1 expression by activated PPAR γ . Nonetheless, mucin expression changes differently in different parts of the female reproductive tract in response to steroid hormone influences. Thus, regulation of these genes is tissue specific and complex. MUC1 appears to be differentially spliced as well, since forms lacking the extracellular tandem repeats or the cytoplasmic tail can also be detected in certain cell types. It is not clear what fraction of the total MUC1 pool is contributed by these splice variants or exactly what functions these forms play in the implantation process. Other mucins, including MUC3 and MUC4, also undergo alternative splicing to generate transmembrane or soluble variants.

Transport and Metabolism

Mucin assembly involves synthesis and transit of the core protein from the rough endoplasmic reticulum through the Golgi apparatus where most of the glycosylation occurs. Subsequently, the fully assembled mucin is transported to the cell surface. The entire process described above takes 60–90 min for the average mucin molecule in several cell types. Both MUC1 and MUC4 are synthesized from a single mRNA, but are proteolytically cleaved during their biosynthesis, resulting in the formation of stable heterodimers of their respective ectodomains and transmembrane/cytoplasmic tail domains. MUC1 undergoes an autoproteolytic cleavage within the sea-urchin sperm protein, enterokinase, and agrin (SEA) module in the ectodomain. While the exact nature of the association of the heterodimers is not clear, in the case of MUC1 the complex is not dissociable by a number of agents, including urea, heating, high salt, or reducing agents; however, it is readily dissociable by sodium dodecyl sulfate in a variety of normal cells and tumor-derived cell lines.

After arriving at the cell surface, MUC1 undergoes one of the following three fates:

1. it can be recycled and further sialylated intracellularly and returned to the cell surface, or
2. it may be endocytosed and degraded in acidic compartments, presumably lysosomes, or
3. the ectodomains may be released or shed from the cell surface.

Although the process of mucin shedding has been recognized for many years, the identity of the sheddases mediating this release has remained elusive. Recent evidence indicates that tumor necrosis factor- α -converting enzyme/ADAM metallo-peptidase domain 17 (TACE/ADAM17) and membrane type 1 matrix metalloproteinase (MT1-MMP) as such sheddases. TACE/ADAM17-mediated shedding of MUC1 results in a cytoplasmic tail fragment that serves as a substrate for γ -secretase and can undergo rapid intramembranous proteolysis. Mucin shedding is a property of both normal and tumor cells and, indeed, serum levels of shed ectodomains are used as markers of tumor burden in certain cancers. Shedding also may be stimulated by physiologically relevant agents, for example, cytokines, as well as other compounds, such as phorbol esters. In the context of embryo implantation, stimulation of mucin shedding may be the key method to create cell-surface access to embryo receptors in certain species, for example, rabbits and humans. In other species, shedding may be coupled with decreased mucin expression to clear the apical cell surface in preparation for embryo attachment.

Summary and Future Directions

The process of embryo implantation is under the control of the actions of ovarian steroids that coordinate the development of the embryo with the maturation of the endometrium. A panorama of receptors and binding factors may participate in a redundant fashion to promote embryo–uterine interactions during implantation. Nonetheless, under most conditions, the thick mucin coat that covers the apical surface of the uterine epithelium serves not only as a protective barrier to infection and enzymatic digestion, but also as a barrier to embryo attachment. This barrier must be removed in order for embryo attachment to occur. In many species, the same ovarian steroids that coordinate the implantation process also control mucin expression, leading to the loss of the mucin coat at the time of implantation. In other species, including humans, ovarian steroids do not downregulate mucin expression. Rather, localized activation of mucin shedding at the cell surface has been proposed as a mechanism to create access to the apical cell surface of the uterine epithelium. Identification of factors responsible for regulation of mucin gene expression as well as shedding may provide novel avenues to promote fertility as well as improve protection of the reproductive tract from infectious agents. In addition, the findings that certain transmembrane mucins interact with intracellular signal trans-

ducing molecules suggest novel roles for these complex glycoproteins in sensing and triggering responses to the extracellular environment and indicate opportunities for novel therapeutic interventions to modulate mucin expression in normal and pathological states.

Multidrug Resistance Membrane Proteins

N C Rockwell, University of California at Davis, Davis, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

ATP-binding cassette (ABC) transporter A member of a family of membrane transport proteins distinguished by a conserved sequence (the ABC). Most ABC transporters directly couple ATP hydrolysis to vectorial transport across biological membranes.

Cross-resistance The general phenomenon whereby a cell selected for resistance to one toxin simultaneously acquires resistance to other toxins not presented to the cell; multidrug resistance is a special case of cross-resistance.

Homolog A protein with significant sequence similarity to another protein, either across its entire length or in certain regions or domains.

Nucleotide-binding domain (NBD) A conserved domain, or discretely folded protein structure, which is part of an ABC transporter. The ABC signature sequences reside in the NBD, and NBDs power transport by binding and hydrolyzing ATP.

Polyspecific Having very broad specificity, with minimal overlap in chemical structure.

MDR1 and the Clinical MDR Phenotype

Chemotherapy remains one of the main approaches available for the treatment of cancer. In chemotherapy, chemical compounds preferentially more toxic to cancer cells are administered to the patient. However, cancer cells are genetically and biochemically quite similar to the surrounding tissue, so a fairly narrow range of concentrations is available for the administration of chemotherapeutic drugs, and factors that reduce the accumulation of such drugs within the actual cancer cell will confound treatment. In practice, chemotherapy often fails or offers only a brief respite, and there are a number of mechanisms for such failure. In one such mechanism, the cancer cell may express one or more proteins that directly export the drug, preventing its accumulation to effective concentrations. The genetic instability of cancer cells permits them to alter expression of proteins or to develop mutated forms of proteins during the course of the disease, and the use of chemotherapy is in essence a selection for those cancer cells which are able to resist the drug or drugs used. Once such resistant cells arise, continued treatment will cause the resistant cells to dominate the population of cancer cells over time. Often, the appearance of resistance to one chemotherapeutic drug is accompanied by simultaneous appearance of resistance to a range of other drugs that are not structurally related, leading to the name multidrug resistance (MDR). The appearance of MDR is a major complication in chemotherapy.

The Discovery of MDR1

One can study MDR by selecting for resistance to a given drug in tissue culture. In the laboratory of Victor Ling, cells selected for resistance to the chemotherapeutic drug colchicine were shown to have simultaneously gained cross-resistance to a number of other compounds with no obvious overlap in chemical structure. Cross-resistance correlated with the expression of an integral membrane protein named P-glycoprotein or Mdr1, which was subsequently shown to be encoded by the *MDR1* gene (also known as *ABCB1*) through the work of Michael Gottesman and others. The amino acid

sequence encoded by *MDR1* has the hallmarks of an adenosine triphosphate (ATP)-binding cassette (ABC) transporter: the sequence contains a membrane-spanning region with six transmembrane segments followed by a nucleotide-binding domain (NBD) containing the ABC followed by another membrane-spanning region and a second NBD. *MDR1* is thus predicted to be a fully functional transporter in the absence of other proteins. Later studies have confirmed that Mdr1 is an ATP-dependent pump that extrudes drug molecules from the cell.

Clinical Relevance of MDR1

In the years since the discovery of *MDR1*, much research has focused on its role in the clinical outcomes of patients. The idea behind this work can be summarized in two questions: first, does expression of *MDR1* actually correlate with the results of treatment, and second, does blocking *MDR1* function alter the results of treatment for the better? The answer to the first question has proved to be complex. For certain types of cancer, there is clear evidence that *MDR1* is a significant factor in the outcome of treatment. However, evidence for a role for *MDR1* in other types of cancer is much weaker, even in more recent studies. Complications arise in answering this question, such as the role of other transporters in MDR, individual variation in the level of *MDR1* present, and similar individual variation in the presence of any mutations in the *MDR1* sequence. Nonetheless, at this point it seems clear that *MDR1* is a clinically relevant factor in treating certain cancers, and new genetic screening approaches are being developed to permit a finer diagnosis of whether *MDR1* might be a complication in treating other cancers in particular individuals. The answer to the second question has proved to be even more complex. Some studies have reported that blocking MDR function can improve the results of treatment, but others have argued that such inhibition has no effect. Factors which lead to these disparate results include the frequent lack of surrogate assays ensuring that *MDR1* is truly being inhibited, the lack of examination of other transporters in the patient sample populations, and the observation that blocking *MDR1* can increase

the toxicity of chemotherapeutic drugs to the patient and thereby alter the outcome of chemotherapy indirectly.

Structure and Function of MDR1

MDR1 is a member of subfamily B of the ABC transporter superfamily and functions at the plasma membrane. Like most ABC transporters, MDR1 hydrolyzes ATP at the NBDs, and this hydrolysis is coupled to transport of drugs out of the cell. Thus, MDR1 is a direct active transporter, able to work against a concentration gradient for the molecule being exported without the aid of other gradients by coupling ATP hydrolysis to vectorial transport. Due to the clinical relevance of the MDR phenotype, MDR1 has been the focus of intense study. This work has made

good progress toward understanding how MDR1 actually works to extrude drug substrates from cells. As expected, it has been confirmed that ATP binds to the NBDs of MDR1 and other ABC transporters, while transport substrates such as drugs instead bind to the membrane-spanning regions. For MDR1, this work has now culminated in the determination of structures for mouse MDR1 with and without bound inhibitors in 2009.

The Structure and Transport Cycle of MDR1

The overall structure of the protein exhibits two approximately symmetrical halves (Figure 1(a)) and is not substantially changed upon inhibitor binding. The distribution of charged residues on the protein permits assignment of an approximate plane for the hydrophobic part of the lipid bilayer in which

Figure 1 Structure of MDR1. (a) The crystal structure of MDR1 (PDB accession 3G60) is shown with the approximate hydrophobic membrane bilayer indicated by horizontal black lines. The left and center views are colored from the N-terminus (blue) to the C-terminus (red). The bound inhibitor (*R, R, R*)-QZ59 is shown as a space-filling model within the drug-binding pocket. This pocket is not accessible to the extracellular medium or outer leaflet of the bilayer, but it can readily be accessed from the inner leaflet. The approximate position of ATP within one of the two NBDs was determined by superimposing the structure of the HisP NBD (PDB accession 1B0U) onto the MDR1 NBD, and is shown as a space-filling model. The right view shows the backbone in gray, with acidic (Asp, Glu: red) and basic (Arg, Lys: blue) residues shown in stick representation. Charged residues are absent from the region presumed to interact with the hydrophobic portion of the membrane. (b) A cartoon schematic of the MDR1 structure is shown to illustrate the overlapping architecture of the transmembrane segments, in which segments from both halves of the primary sequence are incorporated into each structural half. The protein is color-coded from the N-terminus (blue) to the C-terminus (red), as in (a), and the inter-domain linker connecting the two halves (not resolved in the structure) is shown as a dashed line. (a) PDB accession 3G60: From Aller SG, Yu J, Ward A, et al. (2009) Structure of P-glycoprotein reveals a molecular basis for poly-specific drug binding. *Science* 323: 1718–1722. PDB accession 1B0U: From Hung LW, Wang IX, Nikaido K, et al. (1998) Crystal structure of the ATP-binding subunit of an ABC transporter. *Nature* 396: 703–707.

MDR1 resides. Interestingly, while the primary amino acid sequence of MDR1 suggests such a symmetrical arrangement, the two membrane-spanning regions observed in the structure are composed of individual transmembrane helices from both halves of the primary sequence (**Figure 1(b)**). Inhibitors bind in a large hydrophobic cavity well situated for lateral access from the inner leaflet of the membrane but not accessible to the outer leaflet. ATP would bind to NBDs, which can transiently dimerize during the transport cycle. Comparison of this structure with the structures of other ABC transporters permits the development of a conceptual transport cycle (**Figure 2(a)**). Drugs partition into the plasma membrane from the extracellular medium due to their hydrophobic character. MDR1 is resting in an inward-facing orientation, such

that drug molecules diffuse laterally in the inner leaflet and enter the MDR1 substrate pocket. In the inward-facing conformation, the drug-binding pocket is not accessible to the outer leaflet or the extracellular medium. Drug binding apparently stimulates ATP binding, implying a cross-talk between the membrane-spanning domains and the NBDs. Structural studies of the MDR1 catalytic cycle from the laboratory of Chris Higgins indicate that major conformational changes take place upon ATP binding, and subsequent crystallographic characterization of other ABC transporters has confirmed that bound ATP switches the transporter to an outward-facing conformation. From this outward-facing conformation, drugs are able to diffuse out of the pocket into either the outer leaflet or the extracellular medium, but they

Figure 2 Polyspecific transport of hydrophobic substrates by MDR1. (a) The inhibitor-bound inward-facing structure of MDR1 (left, PDB accession 3G5U) and the nucleotide-bound outward-facing structure of the bacterial ABC transporter MsbA (right, PDB accession 3B60) are shown in the plane of the plasma membrane (black lines) in a hypothetical transport scheme. Drug molecules (red circles) are exported from the cell in four conceptual steps: (1) the hydrophobic character of the drug permits it to cross to the inner leaflet of the plasma membrane; (2) it then enters the substrate-binding pocket of MDR1 via lateral diffusion; (3) ATP then binds and triggers a change to the outward-facing conformation; and (4) the drug then diffuses off MDR1 into either the outer leaflet or the extracellular medium. To have a complete cycle, ATP hydrolysis would then occur and reset MDR1 to the inward-facing state. (b) Structures are shown for three molecules which interact with MDR1: colchicine, originally used in selecting for resistant cell lines that overexpressed MDR1; etoposide, whose pharmacokinetics are regulated by MDR1, MRP2, and MRP3; and (*R,R,R*)-QZ59, one of two inhibitors which has been co-crystallized with MDR1 to permit examination of the MDR1 substrate-binding pocket. (a) Left, PDB accession 3G5U: Aller SG, Yu J, Ward A, et al. (2009) Structure of P-glycoprotein reveals a molecular basis for poly-specific drug binding. *Science* 323: 1718–1722. Right, PDB accession 3B60: Ward A, Reyes CL, Yu J, Roth CB, and Chang G (2007) Flexibility in the ABC transporter MsbA: Alternating access with a twist. *Proceedings of the National Academy of Sciences of the United States of America* 104: 19005–19010.

are no longer able to access the inner leaflet. In MDR1, it is thought that ATP hydrolysis may subsequently serve to reset the transporter and restore the inward-facing conformation. This is in marked contrast to the roles reported for ATP hydrolysis in the distantly related cystic fibrosis transmembrane conductance regulator, an ABC protein which functions as an ATP-gated ion channel rather than as an active transporter and which is mutated in the genetic disease cystic fibrosis.

The Conundrum of MDR1: Broad Specificity with High Affinity

A very wide range of hydrophobic compounds can serve as substrates for MDR1, without obvious structural motifs that distinguish substrates from nonsubstrates (Figure 2(b)). In spite of this, MDR1 is able to transport these compounds with seemingly high affinity (low K_M). Paradoxically, conventional enzymology dictates that high affinity is achieved via extensive interactions between enzyme and substrate, implying conserved structural features in the substrate. However, hydrophobic substrates accumulate in the membrane at much higher concentrations than in the total volume, and such substrates can bind to the inward-facing conformation of MDR1 from the inner leaflet of the plasma membrane. This means that the apparently high affinity of MDR1 for its substrates is misleading and allows a suitably hydrophobic binding pocket to accommodate many substrates in slightly different binding modes with only modest affinity and without making extensive enzyme–substrate contacts. MDR1 is thus a polyspecific transporter, meaning that it has very broad specificity but does actually recognize specific features of its substrates.

Other MDR Membrane Proteins

In addition to MDR1, other ABC transporters have been identified as clinically relevant MDR membrane proteins. Moreover, with the availability of an ever-increasing number of sequenced genomes, it is possible to identify all the ABC transporters within a given organism. This permits the experimentalist to ask whether a given protein can function as an MDR transporter by expressing it in tissue culture or some other recombinant system.

MDR Protein 1

MDR protein 1 (MRP1 or *ABCC1*) was isolated by Susan Cole and Roger Deeley as a protein implicated in MDR in lung cancer cells. MRP1 belongs to subfamily C of the ABC transporters. Whereas MDR1 transports drugs without the need for any chemical modification, MRP1 and other ABC transporters of subfamily C frequently transport drugs that have first been chemically conjugated to glutathione or glucuronic acid. Exceptions to this rule are sometimes co-transported with unlinked glutathione molecules. As with MDR1, the presence of MRP1 correlates with clinical outcome for certain cancers.

ABCG2

ABCG2 (also called MXR or BCRP) was isolated by several labs as a transporter implicated in drug resistance in breast

cancer cells. It belongs to the G subfamily of ABC transporters. The specificity of ABCG2 seems more narrow than that of MDR1 or MRP1, but chemical conjugation of drugs is not required. There are thus at least three transporters thought to be important in the presentation of clinical MDR, any or all of which may be upregulated or mutated in individual tumors.

Homologous Transporters Not Associated with Drug Resistance

Each transporter associated with clinical drug resistance has close relatives not associated with such resistance. For instance, the two closest relatives of MDR1 are MDR3 (encoded by the *ABCB4* gene) and BSEP (encoded by *ABCB11*). Although both proteins exhibit weak drug-efflux activity in tissue culture or *in vitro*, not even one has been clinically implicated in drug resistance. The closest relative to MRP1 is MRP3, which can also confer weak drug resistance when overexpressed in tissue culture. Another relative, MRP2, can be amplified in cell lines selected for resistance to cisplatin and has been detected in clinical samples, but its importance in clinical MDR is not yet clear. Similarly, at least two relatives of ABCG2, ABCG5 and ABCG8, are not implicated in drug resistance.

Physiological Functions of MDR Transporters

While the existence of MDR membrane proteins complicates chemotherapy, such proteins are actually advantageous for organisms in the absence of cancer. As we eat, a number of molecules are ingested that are not part of the normal human metabolism, and such polyspecific transporters can play a key role both in facilitating their excretion and in creating safe havens from such compounds within the organism. We are also beginning to understand the biological functions of homologous transporters that do not contribute to clinical MDR. Examination of the tissue distribution of different transporters provides valuable information about transporter function. The development of knockout mouse models has also been invaluable in such studies, because such models allow phenotypic analysis of null alleles in a genetically tractable organism that retains much of the complexity of human biochemistry and physiology.

The Physiological Role of MDR1

Homozygous *mdr1*^{−/−} knockout mice have altered ability to withstand and excrete toxic compounds known to be MDR1 substrates. This is consistent with the idea that MDR1 is normally responsible for extrusion of toxic metabolites or xenotoxins from cells to allow facile excretion from the body. MDR1 is found at high levels in the blood–brain barrier, presumably forming a safe haven within the organism for the metabolically reduced neurons of the central nervous system. This population of MDR1 has important consequences for drug delivery across the blood–brain barrier, and the use of MDR1 inhibitors to improve bioavailability within the central nervous system is attracting increasing attention.

The Physiological Role of MRP1

As with MDR1, at least one physiological role of MRP1 is the removal of various toxins from the body. MRP1 expression is quite widespread. This protein has a physiological role in the secretion of leukotrienes, and this has been shown to have implications for response to bacterial lung infections. Recently, MRP1 has also been implicated in determining the tissue distribution of cobalamin (vitamin B12).

The Physiological Role of ABCG2

ABCG2 is expressed in intestine and placenta as well as in a side population of hematopoietic stem cells. It is likely to play a role in detoxification, and it has also been recently shown to act as a glutathione transporter, implicating it in maintaining redox balance.

The Physiological Functions of Homologous Transporters

MDR3 and BSEP (the two closest homologs of MDR1) are both implicated in proper function of the liver: MDR3 is an outward-directed transporter for the membrane phospholipid phosphatidylcholine, and BSEP is a bile salt exporter. Mutations in the genes encoding these two proteins interfere with proper secretion of bile, and such mutations are associated with different subtypes of progressive familial intrahepatic cholestasis. MRP2 is the pump responsible for exporting a wide range of anionic conjugates across the apical membrane of polarized cells, and both MRP2 and MRP3 have been proposed to play important roles in the pharmacokinetics of the chemotherapeutic drug etoposide even though they are not associated with clinical MDR. The ABCG2 homologs ABCG5 and ABCG8 form a functional heterodimer which is responsible for the export of plant sterols from the cells of the intestine into the intestinal lumen.

MDR as Part of a Broader Picture

The phenomenon of MDR is by no means unique to mammalian cells. The ABC transporter family is ubiquitous, and every eukaryotic organism examined to date has its own cohort of these proteins. Examples of such ABC transporters from other organisms implicated in drug resistance or detoxification include AtMRP proteins from *Arabidopsis thaliana*, Pdr5 from *Saccharomyces cerevisiae*, and PGPA from *Leishmania*. This

phenomenon is not unique to eukaryotes; the bacterium *Lactococcus lactis* expresses an MDR1 homolog, LmrA, which is able to complement the loss of MDR1 function in mammalian cells. There are also similarly polyspecific drug exporters belonging to other families of transport proteins, such as AcrB from *Escherichia coli*. Thus, mammalian MDR membrane proteins are a special case of a general theme in biology: removal of a wide variety of toxic compounds from the cell via a small number of polyspecific transport proteins. This principle also casts new light on antibiotic resistance, because overexpression or mutation of a transport protein to acquire resistance to an unnecessary or ill-chosen antibiotic may also imply acquisition of cross-resistance to others.

Glossary

Agonist A drug which binds to a receptor and mimics the actions of a natural transmitter.

Antagonist A drug which binds to a receptor and blocks the action of an agonist.

G proteins A family of proteins which bind guanosine triphosphate and which couple receptors to signaling proteins such as ion channels, adenylyl cyclase, and phospholipase C.

Neurotransmitter Chemical signal released by a neuron.

Introduction

Acetylcholine (ACh) is an important neurotransmitter in both the central and peripheral nervous systems. ACh is synthesized in the cytoplasm of nerve terminals by the enzyme choline acetyltransferase, and is then transported into synaptic vesicles. Depolarization of the nerve terminal causes an influx of calcium into the nerve terminal and evokes the release of ACh into the synaptic cleft; the release of ACh can be blocked by botulinum toxin. The actions of ACh are terminated by the enzyme acetylcholinesterase, which hydrolyzes ACh. The activity of acetylcholinesterase can be inhibited by drugs such as neostigmine and the nerve gas agent sarin.

ACh is released from a nerve terminal and binds to a receptor on the cell surface of a target cell to allow transfer of information across a chemical synapse. Sir Henry Dale, in 1914, divided receptors for ACh into two classes based on their distinct pharmacological properties, nicotinic and muscarinic. Muscarinic ACh receptors (mAChRs) are present on central and peripheral neurons, and in such target organs of the parasympathetic nervous systems as cardiac and smooth muscle, and many exocrine glands. The binding of ACh to mAChR can be blocked by antagonists such as atropine.

The mAChR Gene Family

While pharmacological and biochemical analyses suggested, for many decades after Dale's classification, that there was only a single type of muscarinic receptor, drugs were eventually developed that distinguished between muscarinic receptors in different tissues. For example, gallamine was an antagonist at nicotinic receptors that selectively blocked muscarinic receptors in the heart compared to other tissues, while pirenzepine blocked mAChR in certain neurons with higher affinity than in the heart. These studies indicated that there were multiple pharmacologically distinct muscarinic receptors. In the 1980s, mAChR were purified from both heart and brain, which allowed the isolation of complementary DNA (cDNA) and genomic clones encoding the mAChR. There are five subtypes of mAChR, termed M_1 , M_2 , M_3 , M_4 , and M_5 , which are encoded by distinct genes and differentially expressed in various organs and parts of the nervous system (Table 1).

Muscarinic Receptor-Mediated Signal Transduction

Muscarinic Receptors Signaling Utilizes G Proteins

While nicotinic ACh receptors are ligand-gated ion channels (i.e., the same protein both binds ACh and acts as an ion channel), mAChRs are members of the G-protein-coupled receptor (GPCR) superfamily. G proteins are a family of guanosine triphosphate (GTP)-binding heterotrimeric proteins (they consist of three nonidentical subunits) and they couple receptors to various effector proteins, such as adenylyl cyclase, phospholipase C, and ion channels. In the inactive state, guanosine diphosphate (GDP) is bound to the α -subunit. The binding of ACh to mAChR promotes the dissociation of GDP and the binding of GTP to the α -subunit. This, in turn, causes the dissociation of the α -subunit from the $\beta\gamma$ -subunits; both the α - and $\beta\gamma$ -subunits can interact with effector proteins to regulate their activity. The α -subunits have GTPase activity which can be increased by the action of regulator of G-protein signaling (RGS) proteins. This hydrolysis of GTP to GDP promotes the reassociation of the α - and $\beta\gamma$ -subunits and terminates signaling unless ACh is still present to reinitiate the signaling cycle.

Muscarinic Receptor-Mediated Regulation of Second-Messenger Pathways

The mAChR can be divided into two groups on the basis of both sequence similarities and functional responses. The M_1 , M_3 , and M_5 receptors preferentially couple to the G_q family of G proteins, whose α -subunits can activate phospholipase C (PLC). PLC activity produces two intracellular second messengers: inositol trisphosphate, which causes release of calcium from intracellular stores, and diacylglycerol, which activates protein kinase C. The increased intracellular calcium, in turn, can produce many potential effects, such as activation of protein kinases, activation or inhibition of adenylyl cyclase, activation of phosphodiesterases, and activation of nitric oxide synthetase, which can result in increased intracellular cyclic guanosine monophosphate (cGMP) levels. The M_2 and M_4 receptors preferentially couple to the G_i family of G proteins to inhibit adenylyl cyclase activity, thus lowering intracellular cyclic adenosine monophosphate (cAMP) levels. The types of signals produced by any mAChR can depend on both the level

Table 1 Subtypes of muscarinic receptors

Subtype	Number of amino acids	G-protein family	Some tissues with high expression
M ₁	460	G _q	Cortex, hippocampus, striatum
M ₂	466	G _i /G _o	Heart, cerebellum
M ₃	590	G _q	Exocrine glands, smooth muscles cortex, thalamus
M ₄	479	G _i /G _o	Striatum
M ₅	532	G _q	Hippocampus, ventral tegmentum

The table shows the number of amino acids in the five human mAChR subtypes, the G-protein family to which each receptor preferentially couples, and representative tissues which express the various subtypes.

of receptor expression and the particular complement of signaling proteins expressed in a given cell.

Ion Channels

Many of the physiological responses mediated by the activation of mAChR on excitable cells are due to the regulation of the activity of ion channels. Regulation of ion channel activity can occur by many different mechanisms. Modulation of ion channel activity can occur due to protein phosphorylation. For example, activation of protein kinase C or decreased activity of cAMP-dependent protein kinase (due to inhibition of adenylyl cyclase activity) can lead to decreased activity of sodium and calcium channels, respectively. Activation of tyrosine kinases can regulate potassium channel activity.

Intracellular second messengers can directly regulate ion channel activity. Increased intracellular calcium can increase the activity of calcium-activated potassium channels, and increased cGMP can activate cyclic nucleotide-gated ion channels. In addition, $\beta\gamma$ -subunits released following activation of G_i-family G protein can interact with and regulate ion channel activity. For example, inwardly rectifying potassium channels in the heart are activated in this manner following M₂ mAChR activation.

Muscarinic receptor activation can also regulate ion channel activity by regulating the trafficking of channels to or from the cell membrane. In addition, the activity of some ion channels is regulated by PIP₂, and activation of G_q-coupled mAChR can regulate the activity of these channels by the hydrolysis of PIP₂ due to activation of PLC.

Mitogen-Activated Protein Kinase and Related Pathways

Muscarinic receptors can mediate regulation of a series of protein kinase cascades implicated in a wide variety of processes, including cell growth, differentiation, and apoptosis. These protein kinase cascades lead to activation of the mitogen-activated protein kinases (MAPKs) Erk1 and Erk2, p38 kinase, and c-Jun terminal kinase. The particular cascades which are regulated, the mechanisms responsible for this regulation, and whether there is activation or inhibition of a particular kinase pathway depend on both the specific subtype of mAChR and the cell type the receptor is expressed in.

Structural Studies

Transmembrane Topology

Like other members of the GPCR superfamily, the muscarinic receptors are heptahelical, that is, they have seven helical transmembrane domains, with the amino-terminal extracellular and the carboxyl-terminal intracellular. The amino-terminal domains of the various mAChR subtypes contain asparagine residues which are sites for N-linked glycosylation. Based on the crystal structures determined for rhodopsin and other GPCR and on mutagenesis and structural analyses of the mAChR, it is likely that the transmembrane helices are arranged in a bundle.

Ligand Binding to the mAChR

ACh binds to the mAChR by interacting in a crevice with multiple transmembrane domains in the plane of the membrane. A negatively charged aspartic acid residue in the third transmembrane domain interacts with the positively charged ammonium group of ACh. Mutagenesis experiments have also implicated specific residues in the second, fifth, sixth, and seventh transmembrane domains in the binding of cholinergic ligands. Although classical agonists and antagonists bind to the ACh-binding site (the orthostatic site), drugs which act at a distinct (allosteric) site which either positively or negatively affect ACh binding have more recently been identified.

Regions of the mAChR Involved in Coupling to G Proteins

The binding of ACh to the mAChR induces a conformational change in the receptor which allows it to activate the appropriate G protein(s). The regions responsible for determining the specificity of coupling of the mAChR to G proteins has been determined primarily by construction of chimeric receptors between two mAChR, such as M₂ and M₃, which couple to different G proteins. The membrane proximal portions of the third cytoplasmic loop are the main determinants of the specificity of G-protein coupling, although other regions such as the second intracellular domain may also play a role in mAChR–G-protein interactions. A variety of studies indicate that multiple transmembrane domains of the mAChR and other GPCR undergo conformational changes due to agonist activation.

Muscarinic Receptor Actions In Vivo

Muscarinic Receptor Actions in the Periphery

Muscarinic receptors are present in many target organs of the autonomic nervous system. A generalization based on pharmacological and molecular genetic approaches is that the M₂ receptors are present in heart, while the M₃ receptor is present in smooth muscles and exocrine glands; however, this generalization must be tempered by the presence of additional subtypes of mAChR present in low abundance in both cardiac and smooth muscles and by the possibility of differences in subtype expression between different animal species. Muscarinic receptors decrease the rate and force of contraction of the heart, and increase the tone and motility of the gastro-intestinal and urinary tracts. Muscarinic receptors increase secretions from

salivary and sweat glands, and cause bronchoconstriction and increased bronchial secretions. Intravenous administration of ACh causes vasodilation. This is due not to activation of mAChR on the smooth muscle cells but to activation of the mAChR on the endothelial cells in the blood vessel. mAChR activation results in the production of NO, which then diffuses out of the endothelial cells and into the smooth muscle cells, resulting in relaxation of the blood vessel. Muscarinic receptors in pancreatic beta cells regulate insulin release and glucose homeostasis.

Muscarinic Receptor Actions in the Central Nervous System

Muscarinic receptors play an important role in the central nervous system. Many studies have implicated mAChR in learning and memory. Administration of muscarinic antagonists interfere with performance in many learning and memory tests, and the decreased cognition in patients with Alzheimer's disease is thought to be due, in part, to impaired muscarinic transmission. Both pharmacological and genetic experiments have implicated the M₁ mAChR in memory and learning, although it is likely that multiple muscarinic receptor subtypes play a role in these processes.

Muscarinic receptors in the spinal cord and at supraspinal sites (i.e., the brain) can mediate an analgesic response. Genetic studies in mice show that both the M₂ and M₄ receptors are involved in this anti-nociceptive effect.

Muscarinic receptors have been implicated in many other processes as well. For example, muscarinic receptors regulate the function of the basal ganglia, where multiple subtypes of muscarinic receptors modulate dopaminergic signaling. M₅ receptors are present in the ventral tegmentum and are involved in drug-reward mechanisms. M₃ receptors in hypothalamic neurons regulate growth by stimulating the release of growth-hormone-releasing hormone.

Pharmacological analyses carried out over many years have led to the development of a number of drugs which produce their therapeutic actions by either activating or blocking muscarinic receptors. The increased understanding of the actions of individual mAChR subtypes should be a great aid in the

development of drugs with increased therapeutic actions while decreasing effects at undesired mAChR subtypes.

Glossary

α -Helix The specific helical arrangement of a polypeptide chain formed by repetitive hydrogen bonding between atoms of peptide bonds separated by four amino acids along the chain.

Calmodulin A calcium-binding protein, found ubiquitously in eukaryotic cells, which acts as a calcium-sensitive regulator of many enzymes via its physical binding to the target protein.

Focal adhesions Sites of attachment of cells to the underlying substratum involving specialized protein complexes linking the intracellular actin cytoskeleton to the extracellular matrix.

Heptad repeat A seven-amino-acid sequence, where the third and seventh amino acids are hydrophobic, which tends to form an amphipathic α -helix able to dimerize with another of its kind via the hydrophobic residues to form a double α -helix referred to as a coiled coil.

Protein conformation The three-dimensional form of the protein considering the specific spatial localization of all the atoms in the molecule.

Quaternary structure The three-dimensional conformation of a protein formed by two or more polypeptides.

Sarcomere The functional contractile unit of skeletal and cardiac muscle cells consisting of interdigitating actin (thin) and myosin (thick) filaments.

Overall Molecular Architecture

Although structural variations among the myosins reflect their specific cellular type and function, and also their phylogeny, there is a basic architectural plan followed by these motors (Figures 1 and 2). The protein structure of most myosins can be divided into three principal domains with generic functional homology, constructed from a long polypeptide – the heavy chain – and several small subunits – the light chains. The heavy chain encodes the highly conserved, mechano-chemical generator, usually referred to as the ‘head’ or motor domain, which is a globular domain that contains the actin binding and adenosine triphosphate (ATP) hydrolysis sites, almost universally positioned at the amino terminal portion of the protein. Immediately following the head domain is an elongated, α -helical region in the heavy chain to which calmodulin and/or calmodulin-like light chains bind, forming the ‘neck’ domain. This domain acts as a lever arm to amplify small conformational changes in the motor domain that result in movement of the motor along actin filaments. Myosin light chains are associated with the neck domain and impose an inhibition on the mechano-chemical cycle. In this regard, the neck domain of the heavy chain acts as the regulatory element that triggers the mechano-chemical events when this inhibition is released by either calcium binding to or phosphorylation of the bound light chains. Crystal structures of the head and neck domains from widely distant myosins (vertebrate myosins II and V, *Dictyostelium* myosins I and II, scallop muscle myosin II, and chicken and fruit fly myosins VI) have revealed highly similar atomic structures among them, indicating that the basic molecular machinery for movement is highly conserved.

The region that follows the neck domain is generally called the ‘tail’ and may, or may not, contain a tandem series of a

linear sequence called the heptad repeat, which tends to form a quaternary structure composed of two intertwining α -helices, referred to as coiled coils. Many myosins have dimerized heavy chains due to these coiled coils. The prime example is skeletal muscle myosin II whose tail domain is entirely composed of a coiled-coil motif, which aligns and joins together with other tail domains to form the bipolar, thick filaments of the sarcomere. Other myosins, however, such as myosin I, are without heptad repeats and thus are single headed. The rest of the molecule is referred to as the ‘globular tail’ or targeting domain and is the most structurally diverse part, varying extensively between classes (Figure 3), yet maintaining significant homology within a class. This is a region of interaction with lipid membranes, adaptor proteins, and signaling molecules, important for site recognition, receptor binding, and other specific functions.

Evolutionary Diversity and Phylogenetic Classification

The advent of whole genome sequencing led to the discovery that the myosin family is remarkably diverse. Comprehensive phylogenetic analyses of the conserved myosin motor domain established that there are at least 37 distinct classes of eukaryotic myosin (a class is defined as a group of myosins from several different taxa having highly similar motor domain sequences and tail structures). The classes are each designated by a Roman (or Arabic) numeral, assigned based on the order in which they were identified. The tail regions are unique to each class and are characterized by the specific domain or combination of domains present in this region (e.g., see Figure 3). Some myosins also have N-terminal extensions (e.g., class III) and a few have extremely short tail regions without any notable domains (e.g., class XIV). A large number of myosins with unique tail domains remain unclassified as they are

found only in a small number of closely related species – these are referred to as ‘orphan myosins’. No single myosin class is found in all organisms and there are a number of myosins that are specific to particular kingdoms (such as the class VIII, XI, and XIII myosins found only in plants), suggesting that these motors evolved early and have become highly specialized over time. Class I, II, and V myosins are found in the Fungi, Amoeba, and Metazoans, indicating that these are the ancestral myosins. Remarkably, Prokaryotes and Archae do not appear to possess a myosin or myosin-like motor and it is tempting to speculate that the emergence of myosin motors was an early evolutionary innovation that provided the impetus for eukaryotic cells to gain access to new environmental niches.

Figure 1 Schematic diagram of the head and neck domains of myosin. The relative positions of the actin-binding region to the ATP site in the head and to the light chains in the neck domain are illustrated. The rotation of the neck domain relative to the head domain, which represents the power stroke, is indicated as a curved arrow. The purple structure represents the contribution of the myosin heavy chain to the conformation of the head and neck domains. The yellow structures represent two light-chain proteins that together with the heavy chain extension form the neck domain. Drawn by Claudia Tavares.

It should be noted that the myosin II class is often referred to as ‘conventional’ myosin due to its historical identification and characterization. All other myosins were then collectively designated as ‘unconventional’. However, myosin II is now viewed as being quite unique in that no other class within the myosin superfamily is known to form bipolar filaments. Clearly, the class II myosins have been refined by evolution, culminating in their role in the generation of macroscopic force and velocity of muscle contraction, whereas all other myosins have globular tail regions and are without the propensity for filament formation.

The early appearance of myosins in evolution is consistent with these motors having fundamentally important cellular functions. As the myosin family expanded, organisms often acquired second or third copies of most myosin genes resulting in the expression of two or more genes encoding closely related, but functionally different myosins of the same class (designated by a letter, e.g., myosin IIA and myosin IIB). Each of these myosins has quite similar motor and tail domains but carries small changes in the motor and tail domain that confer slightly different properties to each myosin. Thus, in addition to the large number of myosin classes found in eukaryotes, there are often multiple forms of each myosin class in organisms with their own specific activities and functions.

Mechano-Chemical Features

A description of the molecular mechanism of energy transduction by mechano-enzymes has been a challenge for workers in the field for half a century. The determination of the atomic structures of myosins in several conformational states with nucleotide derivatives bound, in combination with detailed kinetic studies, has brought this goal close to realization. An overall description of the molecular events taking place during the mechano-chemical cycle, which lead to movement and force generation, is given here (Figure 4). There are three elements to keep in mind: first, ATP binds to the myosin motor domain at an active site capable of hydrolyzing it to adenosine diphosphate (ADP) and inorganic phosphate (Pi); second, conformational changes in the myosin structure occur depending on whether

Figure 2 Schematic diagram of three typical myosins representing classes I, II, and V. The purple and yellow structures represent the head and neck domains, respectively, as in Figure 1. The coiled coil is represented by intertwined lines shown in both myosins II and V. The light blue structures represent globular regions in the tail domain of myosin V. Drawn by Claudia Tavares.

Figure 3 Myosin diversity. A selection of different myosin classes (indicated by the Roman numeral in the left column) and where they are found in nature (column to the right) highlighting the diversity of myosins found in nature. The protein domains present at the N-terminus or in the tail region are indicated and regions unique to each myosin are shown as open rectangles or ovals (not drawn to scale). DIL, dilute domain; FERM, band 4.1, ezrin, radixin, moesin domain; MyTH4, myosin tail homology 4; SAH, single alpha-helix; PH, pleckstrin homology domain; SH3, src-homology 3 domain; S/T kinase, serine/threonine kinase domain.

Figure 4 Summary of the kinetic cycle of myosins. The myosin head and neck region are represented by the large and small gray ovals and a segment of a helical actin filament by a series of small circles. The change in the position of the lever arm following ATP hydrolysis is indicated by the black color of the small oval. The biochemical states are indicated above (M, myosin; A, actin; ATP, adenosine triphosphate; ADP, adenosine diphosphate; Pi, inorganic phosphate). While all of the reactions in the cycle are reversible, the favored direction is indicated by the dark line.

ATP or ADP/Pi or no nucleotide is occupying the active site; and, third, myosin binds to filaments of actin (F-actin) either strongly or weakly depending on the molecular conformation of the myosin. Beginning with the binding of ATP to the nucleotide-binding site in the motor domain of myosin, this event puts the myosin into an extended, fully cocked, high-energy conformation, but with low affinity for F-actin, that is, most of the myosins are not bound to F-actin. Myosin, however, quickly hydrolyzes the ATP, which converts myosin into a high-affinity conformation that now strongly binds to F-actin. Triggered by this binding, the reaction products Pi and ADP are sequentially released from the active site accompanied by a major conformational change in the myosin head, which results in the rotation of the lever arm relative to the longitudinal axis of the actin filament. This movement of the lever arm is known as the 'power stroke'. Thus, the conformational change in the myosin molecule, representing a transition from the high-energy to the low-energy state, associated with product release, occurs simultaneously with tight coupling to F-actin and thus converts protein conformational energy into tension development and movement. A return to the weak binding state and disassociation of myosin from F-actin occurs with the rebinding of ATP to the nucleotide site, thus initiating a new cycle. In summary, the mechano-chemical cycle results from the tight coupling of protein conformational energy in the myosin head and neck domains with chemical energy (ATP binding and hydrolysis) and cyclic transitions between strong and weak binding between myosin and F-actin. As presented, this cycle will continue as long as myosin can contact actin and a steady supply of ATP is maintained. (Note that *rigor mortis* results from the interruption of the metabolic supply of ATP that comes with death and represents the strong binding, low-conformational energy state of the actomyosin in muscle at the end of the power stroke.)

Surprisingly, in spite of their highly conserved structure and mechanism of action, the myosin heads differ in a fundamental property related to their mechano-chemical cycle, which affects their cellular function. For example, individual myosin II molecules bind to actin for only a small fraction of the cycle duration, spending a large proportion of their time in the weak binding state. This property is essential for the smooth sliding of myosin filaments in muscle with their arrays of many heads interacting with the organized actin filaments of the sarcomere. On the other hand, at least two myosins (a class V and a class VI myosin) have the property of processivity, that is, they are able to move as individual molecules along actin filaments for some distance without losing contact. Present evidence indicates that these two-headed myosins walk in a hand-over-hand manner along the actin filament, with each head binding to actin for more than 50% of the cycle duration. This property, therefore, allows these myosins, acting alone, to carry cargo without losing a grip on the actin track. All myosins move unidirectionally along polarized actin filaments, with the large majority of myosins moving toward the fast-growing or plus end of actin filaments. However, myosin VI is unique (so far) among all myosins in that it moves in the opposite direction (toward the slow-growing or minus end) along actin filaments. A 50-amino-acid linker between the head and neck domains of myosin VI that reverses the direction of the lever arm seems to be the structural element responsible for this property.

Regulation

The mechano-chemical cycle of myosin must be turned on and off as needed, as is true for all motor proteins. There are several mechanisms to do this, although calcium is the most common

triggering element. For example, in striated muscles a calcium-sensitive system of regulator proteins (tropomyosin and troponins) decorates F-actin and sterically blocks access of the myosin head to the actin sites. Calcium relieves this blockage, such that an increase in its intracellular concentration determines actomyosin activation. For molluscan myosin and vertebrate smooth muscle myosin, regulation is myosin based, in that an inhibitory effect of the neck domain can be relieved by calcium binding to a regulatory light chain or by calcium-activated phosphorylation. Calmodulin has been identified as the light chain for a large number of myosins, and calcium binding to it can trigger the mechano-chemical cycle of myosin and activate motility. However, it should be noted that the role of calcium-calmodulin in myosin regulation is complex and unique to each type of myosin. It has also been demonstrated that conformational folding, that is, the physical approximation of head and tail regions or the doubling over of extended tail structures can control the mechano-chemical cycle, typically inhibiting myosin activity. Again, calcium and/or phosphorylation are also key factors in this regulation.

A Multitude of Cellular Functions

Simplistically, myosins have two functional ends: the motor end, which generates force and movement on actin filaments, and the tail end, which links it to its cargo or to itself to form dimers. Thus, the function of any given myosin is dictated by a combination of the kinetic properties of its motor and the interaction of the tail with its binding partner. The highly diverse nature of the tail domain largely determines the enormous variety of function within the myosin superfamily. For example, the coiled-coil tail of the class II myosins directs both dimerization of the heavy chains and formation of bipolar filaments. It is the tail that specifies the intracellular localization of myosin II filaments where they drive the contraction of skeletal and cardiac muscle or the constriction of the assembled cleavage furrow during cell division. Sorting out the specific functions of individual myosins and myosin classes has been a formidable challenge to researchers in the field. To exemplify the extent of the problem, a single vertebrate cell type – the human intestinal epithelial cell – expresses at least 12 myosins, representing six classes.

Myosins have a broad spectrum of functions, including amoeboid movements, pseudopodia extensions, phagocytosis, exocytosis, cytokinesis, cell gliding over a surface, and other manifestations of plasma membrane dynamics. While the list of known myosin functions continues to grow, myosins appear to have three general roles: intracellular transport, powering large cellular movements, and building or maintaining cellular structures. The most widely studied of myosin functions is organelle transport and many examples of intracellular vesicle and organelle transport that depend on myosin motors have been discovered. The dramatic cytoplasmic streaming in plants is a good example. This process involves class XI myosins, one of only three classes found in plants (the others are class VIII and XIII). The role of class V myosins in the distribution of pigment granules in vertebrate melanocytes and of membrane vesicles in dividing yeast is another example. Several linker proteins have been described that connect myosin motors to

their cargo, such as melanophilin and Rab27a, which link pigment granules to myosin V, and Vac17p, a key component of the myosin receptor on yeast vacuoles. The demonstration in squid axoplasm of translocation of moving vesicles from microtubule tracks to actin filaments suggested that myosins can interact cooperatively with microtubule-based movement for coordinated vesicle transport. These examples serve to illustrate that myosin motors have important roles in the transport of membrane-delimited organelles. In addition, recent evidence shows that myosins also transport macromolecular complexes. Myo4p, a class V myosin in yeast, is directly involved, together with at least two other proteins, in the transport of a specific messenger RNA (mRNA) encoding a transcription factor, to the daughter cell of budding yeast, thus playing an essential role in regulating differential gene expression in this organism.

Myosins contribute to various aspects of cell migration. In mammalian cells, the cytoplasmic class II myosins (IIA and IIB) act in two separate steps of migration – myosin IIB provides contractile force at the rear of the cell and myosin IIA regulates pseudopod extension. The single-headed, class I myosins also contribute to pseudopod extension by binding directly to membranes via the phospholipid-binding regions in their tail domains, thus giving them the ability to orient force generation directly toward membranes. Some of the class I myosins may also contribute to pseudopod extension by recruiting components of the actin polymerization machinery to the leading edge. On the other hand, gliding of Apicomplexa parasites, such as *Toxoplasma gondii*, is powered by the class XIV myosins that are embedded in the space between the plasma membrane and an inner membrane complex. Myosin XIV appears to walk along short, membrane-associated actin filaments, resulting in movement of the membrane against the substrate (similar to a tank tread).

Myosins are required for the formation of specialized actin-filled structures such as filopodia and the maintenance of a related class of structures in the sensory cells of the cochlea called ‘stereocilia’. This may be due to a role for several myosins to localize critical regulators of actin polymerization. For example, filopodia and stereocilia are composed of bundled, parallel actin filaments that grow out from the plasma membrane. Myosin VII and X are required for filopodia formation in several different organisms. Myosin X has been shown to transport vasodilator-stimulated phosphoprotein (VASP), an activator of actin polymerization that binds to the tail of myosin X, to the tips of filopodia and it appears that loss of VASP from the tip abrogates filopodia growth. The class VII and XV myosins play roles in the regulation of stereocilia length. Mice lacking myosin VII have slightly elongated stereocilia and those lacking myosin XV have significantly shorter stereocilia than wild-type mice. The shorter stereocilia found in the myosin XV mutants results from the loss of whirlin, a protein required for full elongation of stereocilia that binds to the tail of myosin XV, from the tips of stereocilia. The ability of these myosins to move along actin filaments toward the membrane allows them to maintain their localization at the tip and aid in the delivery or localization of molecules critical for the growth of the filopodia or stereocilia to the correct place.

One may expect that myosins are end targets for cell signaling. As previously discussed, myosins bind to calmodulin and are indeed activated or modulated by ionic calcium and

protein kinases, all of which are important intracellular messengers for signal transduction pathways. However, it is noteworthy that myosins also seem to participate in signaling pathways themselves, as a kind of motorized signaling device. Evidence for this first appeared upon analysis of tail sequences, where sequence motifs related to cell signaling pathways, such as SH3, PDZ, and PH motifs, were recognized in several distinct myosin classes. These motifs are signals for protein–protein and protein–phosphoinositide binding that participate in the assembly of signaling complexes, although the functional role of myosins containing these signal motifs is still not clear. The tail domain of myosins IX has a region with homology to Rho GTPase, activating proteins (RhoGAPs), which act as molecular switches in the organization of the actin cytoskeleton, particularly in the formation of cell–matrix focal adhesions. Cells lacking myosin IXB fail to spread and polarize, a phenotype that is strikingly similar to cells that have active Rho, suggesting that myosin IX is necessary to turn off Rho signaling. This example illustrates that myosins are not only final targets for cellular signaling but also potential intermediate players in the signaling cascades. Myosins are involved in other cell processes in ways not yet well understood, such as mitotic spindle orientation in yeast, phototransduction in

Drosophila retina, and auditory function of the vertebrate inner ear. Indeed, there is much to be learned about the functional roles of myosin motors throughout the biosphere.

Myosins in Disease

Myosins have fundamentally important cellular roles and it is thus not surprising to find that they underlie the dysfunction observed in a number of human diseases (see [Table 1](#)). The human genome harbors 40 myosin genes, encoding myosins from 12 different classes and mutations in over 10 of these myosin heavy chains have been identified as the cause of hereditary disease. The majority of mutations have been found in the motor domain of a given myosin, although deletions or mutations in tail regions also result in myosin dysfunction and disease. A large number of myosin genes encode class II myosins (12 muscle myosins and three cytoplasmic myosins) and are required for normal muscle function. A major cause of familial hypertrophic cardiomyopathy lies in mutations of the head domain of either of the two cardiac muscle myosin IIs, and mutations in other skeletal myosin genes cause defects in skeletal muscle such as muscle weakness.

Table 1 Human diseases caused by mutations in myosin heavy chains

<i>Gene</i>	<i>Myosin</i>	<i>Disease</i>	<i>Phenotype</i>
Myh2	Adult skeletal myosin IIA	Inclusion body myopathy 3	Dystrophic muscle
Myh3	Embryonic skeletal myosin II	Freeman–Sheldon syndrome (also known as distal arthrogryposis type 2A)	Joint contraction, muscle weakness, fibrosis
Myh6	Cardiac myosin IIA	Cardiomyopathy (familial hypertrophic cardiomyopathy 14, dilated cardiomyopathy 1EE)	Heart failure
		Atrial septal defect 3	
Myh7	Cardiac myosin IIB	Cardiomyopathy (hypertrophic cardiomyopathy 1, dilated cardiomyopathy 1 S)	Premature death due to sudden heart attack
		Myosin storage myopathy	Muscle weakness
Myh8	Perinatal skeletal myosin II	Carney complex	Persistent joint flexing/contracture
Myh9	Cytoplasmic myosin IIA	May–Hegglin anomaly	Macrothrombocytopenias (abnormal platelets)
		Sebastian syndrome	
		Fechtner syndrome	
		Epstein syndrome (MHY9-related diseases)	
		DFNA 17	Sensorineural deafness
Myh11	Smooth muscle myosin II	Thoracic aortic aneurysm/aortic dissection 4	Weakened aortic wall, aneurysm
		Intestinal neoplasia	Colorectal cancer
Myh14	Cytoplasmic myosin IIC	DFNA4	Sensorineural deafness
Myo3A	Myosin IIIA	DFNA30	Progressive hearing loss
Myo5A	Myosin VA	Griscelli syndrome	Pigment dilution, immunologic and nervous system defects
Myo5B	Myosin VB	Microvillar inclusion disease	Diarrhea in infants
Myo6	Myosin VI	DFNA22	Progressive hearing loss
		DFNB37	Congenital hearing loss
		Deafness with hypertrophic cardiomyopathy	Progressive, late-onset deafness accompanied by disease
Myo7A	Myosin VIIA	Usher's syndrome type IB	Deafness, early-onset retinitis pigmentosa
Myo15A	Myosin XVA	DFNB3	Congenital deafness

DFNA, deafness, autosomal dominant; DFNB, deafness, autosomal recessive.

Summary of known human diseases caused by mutations in myosin heavy chains.

Detailed information about alleles and phenotypes can be obtained at OMIM (<http://www.ncbi.nlm.nih.gov/omim/>).

Mutations in several different myosin classes result in deafness, reflecting both the complexity of the sensory cells in the ear and the specialization of myosin function. Usher's syndrome type IB is the most common cause of inherited deaf-blindness in patients and it is caused by mutations in the MyoVIIA gene. Other forms of Usher's syndrome type I result from mutations in proteins that interact or work in concert with MyoVIIA. Mutations in other classes of myosin result in nonsyndromic deafness; these include myosin IIA, IIC, IIIA, and XVA. Mutations in myosin VI were identified in the Snell's Waltzer mouse, which suffers from deafness due to degeneration of the sensory neuroepithelia in the inner ear, and subsequently in human patients. The availability of mouse models for many of these human deafness diseases has provided critical insights into how each myosin contributes to hearing and the identity of their binding partners. Mutations in the two different class V myosins, MyoVA and MyoVB, result in distinct human diseases. Mutations in MyoVA result in Griscelli syndrome, where children exhibit hair hypopigmentation, linked to severe immunological and neurological deficits that frequently lead to early death. As might be expected, mutations in Rab27A, a myosinVA binding partner that links myosinVA to organelles, also cause Griscelli syndrome. In contrast, mutations in MyoVB cause microvillar inclusion disease due to a loss of epithelial cell polarity. Rapid progress in mapping human disease loci in combination with the generation of mouse models suggests that many more connections will be made between human disease and myosin function in the near future.

This article is a revision of the previous edition article by Lincoln R. Potter, volume 3, pp. 1–5, © 2004, Elsevier Inc.

Glossary

Cyclic GMP A cyclic mononucleotide of guanosine that acts as an intracellular second messenger for hormones, such as natriuretic peptides, guanylin, and nitric oxide.

Guanylyl cyclase An enzyme that catalyzes the synthesis of cyclic GMP and pyrophosphate from guanosine triphosphate.

Natriuresis Urinary sodium excretion.

Natriuretic peptides are an ancient family of hormones/paracrine factors that regulate blood pressure, cardiovascular homeostasis, and long bone growth. The mammalian family consists of atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). All three peptides are derived from separate genes, but share a common 17-amino-acid disulfide ring that is required for biological activity. A family of three cell-surface receptors binds natriuretic peptides. Two are receptor guanylyl cyclases, enzymes that catalyze the synthesis of the intracellular second messenger, cyclic guanosine mononucleotide (cGMP), whereas one is a clearance receptor that controls local natriuretic peptide concentrations via constitutive receptor-mediated endocytosis. In this article, the structure, function, and regulation of each hormone and receptor are discussed.

Natriuretic Peptides

Atrial Natriuretic Peptide

ANP was the first natriuretic peptide to be identified. It is also called atrial natriuretic factor or atriopeptin. Pioneering studies by de Bold and co-workers found that intravenous infusion of atrial, but not ventricular, homogenates into rats caused a rapid and dramatic increase in renal sodium and water excretion that was accompanied by reduced blood pressure and increased hematocrits. The peptide responsible for these activities was purified and sequenced from multiple species by several laboratories. The sequence of polypeptide precursors was derived from complementary DNA sequences from several species.

All natriuretic peptides are synthesized as preprohormones. Human preproANP is 151 amino acids in length. Proteolytic removal of the amino terminal signal sequence yields a 126-residue proANP peptide, which is the predominant form

found concentrated in dense atrial granules. Upon secretion, proANP is cleaved by corin, a transmembrane serine protease, to a nonfunctional 98-residue amino-terminal peptide and a 28-residue carboxyl-terminal bioactive peptide. Both fragments circulate in the plasma and are elevated under conditions where vascular volume is increased, such as congestive heart failure. The carboxyl-terminal peptide is the mature form of ANP that mediates the known biological effects associated with the ANP gene ([Figure 1](#)); this peptide contains 28 residues, with a six-residue amino tail and a five-residue carboxyl tail. The majority of ANP gene expressions occur in the cardiac atria, but low-level expressions take place in the kidney. Atrial-wall stretch, reflecting increased intravascular volume, is the dominant stimulus for ANP release. However, several hormones and neurotransmitters such as endothelin, arginine vasopressin, and catecholamines, also stimulate ANP secretion.

In addition to stimulating natriuresis, diuresis, and vasorelaxation, ANP also inhibits renin, vasopressin, and aldosterone release, as well as cell proliferation and hypertrophy. Hence, ANP's short-term (natriuresis, diuresis, vasorelaxation) and long-term (antihypertrophy) effects are generally considered beneficial.

Transgenic mice exhibiting lifelong elevated plasma ANP levels display reduced blood pressure and heart size. In contrast, mice lacking ANP are hypertensive. The initial report describing these animals suggested that ANP regulates blood pressure in a salt-sensitive manner, but a subsequent communication indicated that these same mice were also hypertensive when fed a low-salt diet, consistent with ANP mediating its effects independently of body sodium levels.

ANP is degraded by extracellular proteases and through natriuretic peptide clearance receptor (NPR-C)-dependent internalization and degradation. Neutral endopeptidase (NEP) and insulin-degrading enzyme have been shown to proteolyze ANP.

Figure 1 Schematic representation of natriuretic peptides and their receptors. Black arrows indicate peptide binding to signaling receptors. The blue arrows indicate that they bind the NPR-C, which leads to degradation. Blue circles in natriuretic peptide structures indicate conserved residues. In the kinase homology domain, the black P's indicate phosphorylation sites. Abbreviations: ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; CNP, C-type natriuretic peptide; cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; GC-A, natriuretic peptide receptor A; GC-B, natriuretic peptide receptor B; NPR-C, natriuretic peptide receptor C.

B-Type Natriuretic Peptide

B-type natriuretic peptide was first purified from porcine brain extracts and, therefore, named brain natriuretic peptide. However, subsequent experiments found that the peptide exists in higher concentrations in stressed cardiac tissues and, for this reason, is most often called BNP.

BNP exhibits many of the same characteristics as ANP and is also encoded on chromosome 1. The resulting prohormone contains 134 residues but only the 108-residue prohormone is found in cells because the signal sequence is cleaved during translation. The protease responsible for processing of proBNP to BNP is not definitively known but corin is a reasonable candidate. The bioactive form of human BNP contains 32 residues, with a nine-residue amino tail and a six-residue carboxyl tail.

BNP is expressed along with ANP in the atrial granules, but higher levels of expression occur in cardiac ventricles during periods of cardiovascular stress such as heart failure. In the ventricles, BNP is transcriptionally regulated and constitutively released once it is synthesized. It is not stored in ventricular granules.

Plasma concentrations of BNP in normotensive patients are much lower than those of ANP (about 1 fmol ml^{-1} vs. 10 fmol ml^{-1} , respectively). However, BNP production is elevated to a greater degree in patients with congestive heart failure, and, in extreme cases, plasma concentrations can increase more than 300-fold. This makes BNP a better serum marker of heart failure than ANP.

BNP is degraded by NPR-C-mediated internalization and also by cell-surface proteases. However, BNP is not a good substrate for NEP. Instead, a protease that is inhibited by leupeptin degrades BNP. This reduced degradation by NEP may contribute to the 20-min as opposed to 2-min half-lives for BNP and ANP, respectively.

C-Type Natriuretic Peptide

CNP was initially purified from porcine brain extracts and is the most highly expressed natriuretic peptide in this tissue. Human preproCNP is 126 residues in length. The 103-amino-acid CNP propeptide is processed to either a 53- or a 22-amino-acid form. The bioactive forms of CNP are structurally similar to ANP and BNP, but they lack a carboxyl tail (Figure 1). Furin has been suggested to mediate this final cleavage step. Both the 53- and 22-amino-acid forms have been identified *in vivo*. The 22-amino-acid peptide predominates in fluids such as blood, and the 53-amino-acid version is found mainly in tissues. The bioactivity of the two CNP peptides is similar. CNP relaxes vascular smooth muscle and is a more potent dilator of veins than ANP or BNP. CNP is not natriuretic despite its name.

Homozygous deletion of the gene encoding CNP in mice caused more than half of the offspring to die during postnatal development. Surviving animals exhibited shortened body length and defects in endochondral bone development, which is analogous to human dwarfism. cGMP-dependent protein kinase G II (PKGII) knockout mice also develop dwarfism as a result of impaired endochondral ossification, suggesting that PKGII mediates the CNP-dependent skeletal effects. Consistent with a linear CNP/cGMP/PKGII pathway, the targeted expression of CNP in growth plate chondrocytes cannot increase the longitudinal bone growth or chondrocytic proliferation and hypertrophy in PKGII knockout mice. Chromosomal translocations that increase CNP concentrations in humans cause marfanoid-like skeletal overgrowth.

CNP is the only natriuretic peptide that does not have a C-terminal tail. It does, however, have a 36-residue amino-terminal tail in CNP-55 and a five-residue amino-terminal tail in CNP-22. CNP is degraded by NPR-C-mediated endocytosis and by NEP and insulin-degrading enzyme.

Natriuretic Peptide Receptors

There are three known natriuretic peptide receptors. Guanylyl cyclase A (GC-A) and guanylyl cyclase B (GC-B) are transmembrane guanylyl cyclases, whereas the NPR-C does not possess any known enzymatic activity. Instead, NPR-C controls the local concentration of natriuretic peptides that are available

to bind GC-A and GC-B through receptor-mediated internalization and degradation.

Guanylyl-Cyclase-Linked Natriuretic Peptide Receptors

ANP and BNP elicit their effects through GC-A. CNP activates GC-B. Both guanylyl-cyclase-linked receptors have five homologous domains: the extracellular ligand-binding domain, a membrane-spanning region, a kinase homology domain (KHD), a hinge dimerization region, and C-terminal guanylyl cyclase catalytic domain (Figure 1).

The ligand selectivity for GC-A is $\text{ANP} \geq \text{BNP} \gg \text{CNP}$, whereas the ligand selectivity for GC-B is $\text{CNP} \gg \text{ANP} = \text{BNP}$ (Figure 1). Mice lacking GC-A are hypertensive and develop cardiac hypertrophy and ventricular fibrosis. In addition, they are completely unresponsive to the renal and vasorelaxing effects of ANP and BNP, consistent with GC-A being the sole signaling receptor for these peptides in mice. GC-B mediates the endochondrial ossification effects of CNP. Homozygous inactivating mutations in GC-B cause acromesomelic dysplasia-type maroteaux dwarfism in humans.

Both GC-A and GC-B consist of an approximately 450-amino-acid extracellular ligand-binding domain, a 21-residue hydrophobic membrane-spanning region, and a 566- or 568-amino-acid intracellular domain, respectively (Figure 1). The latter can be divided into a ~250-amino-acid KHD, a 41-amino-acid hinge-dimerization region, and a 250-amino-acid C-terminal guanylyl cyclase catalytic domain.

The GC-A extracellular domain contains three intramolecular but no intermolecular disulfide bonds. Similar cysteine residues are conserved in the extracellular domain of GC-B. Both GC-A and GC-B are highly glycosylated, and several studies suggest that glycosylation is required for proper receptor folding and/or transport of the receptor to the cell surface, but is not required for hormone binding.

Activation of the guanylyl-cyclase-linked natriuretic peptide receptors is incompletely understood. Both receptors are homooligomers in the absence and presence of their respective ligands, indicating that receptor activation does not simply result from ligand-dependent dimerization. However, ANP binding does cause a conformational change in GC-A which brings the extracellular juxtamembrane regions of each monomer closer together. In addition to natriuretic peptides, adenosine triphosphate (ATP) is also required to maximally activate the guanylyl-cyclase-linked receptors in broken cell preparations. In the resting state, both GC-A and GC-B are highly phosphorylated on multiple serines and threonines within their KHD domains (Figure 1). Mutation of any of these phosphorylated residues to alanine in order to mimic a dephosphorylated serine or threonine results in decreased ANP- or CNP-dependent guanylyl cyclase activity. Furthermore, receptors containing alanine substitutions at four or more phosphorylation sites are completely unresponsive to hormone. Both GC-A and GC-B are desensitized by dephosphorylation.

The Natriuretic Peptide Clearance Receptor

In addition to GC-A or GC-B, all three natriuretic peptides bind NPR-C, which is found as a disulfide-linked homodimer

in cells. NPR-C has a large amino-terminal extracellular ligand-binding domain, a single transmembrane domain, and an intracellular domain that contains only 37 amino acids (Figure 1). It not only binds ANP, BNP, and CNP with similar affinities, but can also bind tightly to several smaller carboxyl-terminal and ring-deleted peptide analogs that do not bind well to GC-A or GC-B. C-ANF (atrial natriuretic factor), the prototypical form of these peptides, is sometimes used to distinguish NPR-C from GC-A in both binding and cGMP stimulation assays.

NPR-C is the most abundant natriuretic peptide receptor on the surface of most cells, and its primary function is to remove natriuretic peptides from circulation via receptor-mediated internalization and degradation, thereby controlling the local concentrations of the natriuretic peptides that are available to bind GC-A and GC-B. Like many nutrient receptors, NPR-C internalization is constitutive, that is, it is not increased by natriuretic peptide binding. In addition to its clearance role, NPR-C has also been implicated in signaling, possibly in a G-protein-dependent manner. However, mice lacking NPR-C displayed a reduced ability to clear ^{125}I -ANP from the circulation, but no reduction in known signaling functions. In fact, pathways activated by GC-A and GC-B were increased in these animals.

Natriuretic Peptide Therapies

The cardiac natriuretic peptides, ANP and BNP, trigger natriuresis and diuresis, which decreases vascular volume and allows the circulatory system to compensate for the failing heart. In addition, they also exert local inhibitory effects on the heart by preventing cardiac hypertrophy and fibrosis. Because of these natriuretic and diuretic effects, synthetic forms of ANP and BNP have been approved for the treatment of acute decompensated heart failure.

Synthetic ANP, known as Carperitide, was approved for use in patients in Japan in 1995. Human BNP, synthesized recombinantly in *Escherichia coli*, is called Nesiritide and was shown to be a better renal activator than Carperitide in heart-failed dogs. Based on positive results from the Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) trial, Nesiritide was approved for the treatment of acute decompensated heart failure in the United States in 2001. Subsequently, the safety of Nesiritide was questioned. Complicated statistical manipulation of clinical trial data from multiple studies, called meta-analysis, led researchers to suggest that Nesiritide worsened patients' renal function and increased the likelihood of death. However, the Follow-Up Serial Infusion of Nesiritide (FUSION) trials, specifically designed to investigate the potential adverse renal effects of Nesiritide in patients with advanced heart failure, found no evidence of decreased renal function. Unfortunately, they also found little clinical benefit of the drug.

One possibility for the negative results is that congestive heart-failure patients may have developed resistance to natriuretic peptides. Consistent with this idea, mice with heart failure were shown to have reduced levels of GC-A but not GC-B. New natriuretic peptide-based therapies are focusing on chimeric natriuretic peptides that activate both receptors.

Glossary

Glycoside clustering effect When glycosides are bundled together at proper distances, the total effect can be much greater ($>10^6$ -fold) than the simple sum of individual glycoside.

Neoglycoconjugates The original term of neoglycoproteins has now been expanded, and the term neoglycoconjugates has been introduced to encompass all the glyco-modified materials.

Preparation

Direct Coupling of Oligosaccharides to Proteins

The easiest method is to attach naturally available oligosaccharides to the amino groups of proteins. This process does not require any chemical manipulations other than the conjugation process by reductive amination. Some of the readily available di- and oligosaccharides include: lactose, maltose, cellobiose, melibiose, *N*-acetyl-lactosamine, di-*N*-acetyl-chitobiose, and a number of milk oligosaccharides. An example of coupling of lactose by reductive amination to protein using sodium cyanoborohydride or pyridine borane as reducing agent, which preferentially reduces aldimine (Schiff's base) over aldehyde, is shown in [Figure 1](#). This method relies on the fact that reducing sugars in acyclic aldehyde form, although present in a very minor proportion, are in equilibrium with the cyclic forms. As the aldehyde form of oligosaccharide is consumed, more will become available by conversion from the cyclic forms. However, the conjugation by this simple method is a very slow process, requiring several days or longer, because of the low concentration of the aldehyde form of oligosaccharide in solution.

The reductive amination converts the primary amino groups of N-terminus and lysine side chains to secondary amines initially, and eventually to tertiary amines (with two sugar groups attached to a single nitrogen), if both oligosaccharide and reducing agent are present in excess. It is important to note that after such a reaction, the reducing terminal sugar of the oligosaccharide will become acyclic, and for this reason, conjugation with monosaccharide is meaningless. The shortcoming of this approach, in addition to long reaction time mentioned above, is the limited availability of suitable oligosaccharides. However, the number of commercially available oligosaccharides that are naturally derived or synthetically prepared has been steadily increasing.

Using Synthetic Carbohydrate Derivatives

Neoglycoproteins prepared by direct conjugation of oligosaccharides sometimes can be disadvantageous, due to sugar residues that are recognition target being too close to the protein surface. Synthetic carbohydrate derivatives would expand the scope of neoglycoprotein considerably both in terms of sugar

structure and its disposition on the protein surface. The procedures can be totally synthetic or can be chemical modifications of naturally available glycans either in a free sugar form or linked to a group such as peptide. A few of the popular procedures are presented below.

Aromatic glycosides

Commercially available *p*-aminophenyl glycosides are convenient derivatives for making neoglycoproteins either by diazo-coupling to tyrosine side chains or via transformation into isothiocyanate (reaction with thiophosgen), which then reacts with amino groups. *p*-Nitrophenyl glycosides, commonly used chromogenic glycosides, are available in even wider variety, and can be easily reduced to the corresponding *p*-aminophenyl glycosides. A shortcoming of these derivatives is that they can increase the hydrophobicity of product neoglycoprotein considerably and consequently may alter the nature of protein and give anomalous results in the probing of carbohydrate function.

Nonaromatic glycosides

The problem of excessive hydrophobicity can be alleviated by the use of derivatives which do not contain aromatic rings and are not as hydrophobic as aromatic glycosides (e.g., [Figure 2](#)). Some of these derivatives are thioglycosides, which have the advantage of being more resistant to most exoglycosidases and also specifically cleavable with mercuric salts. Examples shown in [Figure 2](#) are: (a) sugar imidate reacting with amino groups of protein to produce amidino-type neoglycoproteins; (b) an ω -aldehyde glycoside being coupled to protein via reductive amination; and (c) an ω -aminoalkyl glycoside converted into a squaric acid derivative which can react with amino groups of protein. In both (b) and (c), the length of a glycon can be varied.

Reduced and periodate-oxidized natural oligosaccharides

Synthesis of oligosaccharides having complex structure is still a tedious and difficult task. Therefore, it is prudent sometimes to utilize naturally isolable oligosaccharides, if the quantity of neoglycoprotein needed is not too large. Natural oligosaccharides, pre-existing or obtained from natural glycoconjugates by enzymatic cleavage, can be made more reactive by first reducing them with sodium borohydride (to convert the reducing

Figure 1 Conjugation of lactose via reductive amination.

sugar residue into acyclic alditol) followed by mild periodate oxidation (e.g., 10 mM NaIO₄ for 10 min at room temperature), which will preferentially oxidize acyclic glycols to generate aldehyde group(s) without affecting the rest of the cyclic sugar residues. The newly generated aldehyde can be used in the reductive amination reaction as described above.

Using Other Functional Groups of Proteins

Most of the conjugation methods described above utilize amino groups of proteins for conjugation, which are often abundant and reactive because of the distance from the protein backbone. However, other functional groups such as phenolic, sulfhydryl, and carboxyl groups can also be used for conjugation. Diazo coupling of aryl glycosides to tyrosine side chain has been mentioned earlier. Thiol groups of protein are easy target for oligosaccharide attachment, since chemically mild, thiol-specific reactions are readily available. For example, a heterobifunctional linker with an amino-reacting group on

Figure 2 (a–c) Example of synthetic methods for neoglycoprotein preparations.

one end and a maleimido or iodoacetamido group on the other end is reacted first to an Asn-oligosaccharide (or other glycopeptide) via its amino terminus, which is then reacted with protein thiol groups to produce neoglycoprotein in high yield. Bovine serum albumin (BSA) has a single sulfhydryl group which can be utilized in this way to produce a neoglycoprotein carrying a single oligosaccharide chain of defined structure. An interesting approach is to react glycosylthiol with protein thiol group to form a disulfide bond. This will result in a product quite similar in structure to the natural *N*-glycosylated protein in terms of linkage length.

Use of Glycosyl Transferases

As the number of glycosyl transferases available commercially increases steadily, these enzymes have become a powerful synthetic tool in neoglycoprotein synthesis. The advantage of glycosyl transferases is their exquisite specificity for anomeric configuration as well as the position of attachment. Thus, these enzymes are especially suited for modifying a pre-existing glycan structure (even a monosaccharide) at a specific position. Attachment of terminal α -L-fucosyl group or sialic acid group is a prime example. The enzymatic reaction can be carried out on the oligosaccharide before conjugation or after the conjugation to proteins.

Conjugation of Glycopeptides

For the conjugation of glycan structures from glycoprotein, sometimes it is easier to generate glycopeptide than to generate reducing oligosaccharide. A heterobifunctional crosslinker with a hydrazide and an acetal group at two ends of molecule was devised to react first with amino group of glycopeptide (or any other amino-terminated carbohydrate derivatives) via azide reaction, which is followed by the generation of aldehyde function and then coupling to protein via reductive amination.

In all of these reactions, the level of sugars on neoglycoproteins can be controlled either by the ratio of reagent to protein or by the length of reaction. It should be borne in mind that these modifications generally produce a distribution of different sugar substitution in terms of both position and number. However, the ability to vary the degree of substitution turned out to be a great advantage for probing of carbohydrate function in many biological systems that is not readily available in natural glycoproteins. This is because recognition of carbohydrates often requires multivalency (glycoside clustering effect) in order to manifest its function unequivocally. Neoglycoproteins can readily provide multivalency and thus are powerful ligands for carbohydrate binding.

In addition, neoglycoproteins can be radioiodinated (using the tyrosine side chain) or modified with fluorescent groups, such as fluorescein (using available ϵ -amino group) for easy monitoring.

Applications

Carbohydrate Receptor Analyses

Using neoglycoproteins, one can easily survey sugar-binding receptors (or lectins) in a biological specimen. For example, a series of neoglycoproteins have been used to determine that

alligator hepatic receptor has binding specificity for mannose and L-fucose. The binding of tagged neoglycoproteins (e.g., ^{125}I -labeled) to receptors can be probed both in solution phase and solid phase. Properly labeled neoglycoproteins can be used as cytochemical markers.

Affinant for Isolation

Neoglycoproteins can serve as effective affinants for the isolation of lectins and receptors. For such a purpose, a neoglycoprotein can be conveniently immobilized to a suitable solid phase (e.g., sepharose). In an alternate case, a protein (such as BSA) is immobilized first and then modified with one of the reagents mentioned above to form neoglycoproteins on solid phase.

Substrates for Enzymes

Neoglycoproteins can be used as convenient substrate for enzymes. For example, GlcNAc-BSA adsorbed on microtiter wells was used conveniently as substrate to assay β -galactosyl transferase with great sensitivity, which in turn can be used to assay α -fucosyl transferase.

Targeting Device

Neoglycoproteins can be used to target drugs and other materials to specific organs. For example, Gal- or GalNAc-containing neoglycoproteins, when properly conjugated to drug or anti-sense materials, can be used to target such materials to mammalian liver.

Examination of Glycoprotein Structure/Function Relationship

Carbohydrate chains of glycoprotein can have biological and biochemical function unrelated to specific sugar-lectin interaction. One of the better documented cases is the glycan in the Fc domain of IgG, which is required for interaction with Fc receptor. Neoglycoproteins were prepared by disulfide formation between Cys (in lieu of Asn) in the Fc domain and glycosylthiols of various structures to examine the effect of glycan structure on Fc receptor binding activity. Moreover, if the amino acid sequence and X-ray structure are known, one can place a Cys at different surface locations by genetic engineering, which would provide more latitude in examination of the role of carbohydrates on glycoproteins.

Glossary

Axonal spheroids Accumulations of protein aggregates in axons, usually containing neurofilamentous structures.

Axonal transport The movements of vesicles, mitochondria, and other cytoplasmic structures down the axon, necessitated by the fact that most protein synthesis occurs in the axon and the proteins must sometimes travel long distances to reach the end of the axon. This transport generally occurs by way of motor proteins along microtubules and microfilaments.

Charcot-Marie-Tooth (CMT) disease An inherited neurological disorder that affects the peripheral nerves.

It is named after the three physicians who described it. CMT patients slowly lose the normal use of their limbs as the nerves to the extremities degenerate. There are a large number of different causes for the disease, including the recently identified neurofilament mutations.

Cytoskeleton A network of interconnected cytoplasmic filaments, which consists of microtubules, microfilaments, and IFs.

Transgenic mouse A mouse that has been genetically altered to express a gene that is not normally expressed or to have a gene deleted (also called a knockout mouse).

Introduction

The cytoskeleton of most eukaryotic cells is composed of microtubules, microfilaments, and intermediate filaments (IFs). Microtubules are 25 nm in diameter and are composed of two subunit proteins called α - and β -tubulin, as well as a number of associated proteins, microfilaments are 6–8 nm in diameter and made up of a protein called actin. IFs are intermediate in size between the microtubules and microfilaments. All IF proteins contain a central α -helical rod domain flanked by nonhelical N-terminal head and C-terminal tail domains. The rod domain contains hydrophobic repeats (called heptad repeats) that mediate dimerization by allowing two α -helices to wrap around each other forming a 'coiled coil'. Subsequent polymerization into filaments involves the formation of tetramers and higher-order structures for which the N-terminal head domain is particularly important. Based on their protein sequence similarities and their gene structure, the IF protein family is separated into six or seven types. In the nervous system, IFs are expressed in both neurons and glial cells. In the central nervous system (CNS), astroglial cells express the glial fibrillary acidic protein (GFAP) and sometimes vimentin, whereas oligodendrocytes appear to be one of the few cell types that express no cytoplasmic IFs. In the peripheral nervous system (PNS), Schwann cells express the more ubiquitous IF protein vimentin. Vimentin and GFAP are quite similar in sequence and gene structure and are part of a subfamily of IFs called type III IFs.

Neuronal IFs are the major and most visible filamentous structures in the axons. The number of neuronal IFs is correlated with axon diameter and they are believed to be primary determinants of axon diameter. The neurofilament triplet proteins (NFTPs) are the most ubiquitous IF proteins in neurons; they are present in both central and peripheral nerves. The NFTPs and α -internexin are more closely related to each other than to other IF proteins and are classified together as a

subfamily called type IV IFs. The expression of peripherin predominates in the PNS. Although peripherin is expressed exclusively in neurons, based on its protein sequence homologies and its gene structure, peripherin is more similar to vimentin and GFAP and is, therefore, considered a type III IF. Nestin is the IF protein found in neuroepithelial stem cells, as well as muscle progenitor cells. The protein sequence of nestin is quite unique and nestin is sometimes considered to be a separate type VI IF. However, on the basis of its gene structure, it resembles the other type IV neuronal IFs.

One of the hallmarks of a number of neurodegenerative diseases is the accumulation of neuronal IFs in the form of axonal spheroids. These axonal spheroids have been observed in amyotrophic lateral sclerosis (ALS, also called Lou Gehrig's disease) as well as other neuropathies. A number of recent studies from transgenic mice have indicated that the disorganization of neuronal IFs, especially in the forms of axonal spheroids, can lead to neurodegeneration. The relationship between the various neuronal IF proteins and neurodegeneration is discussed later.

The Neurofilament Triplet Proteins

The NFTPs are composed of three proteins called NFL, NFM, and NFH for neurofilament light, medium, and heavy chain, respectively. NFTPs have been identified in all mammals and birds. The identification of the NFTPs was first done on the basis of studies on the transport of proteins in the axon. To study the transport of particular proteins, early studies used radioactive amino acids to label the newly synthesized proteins, and the nerves were then analyzed to determine the rates at which different proteins move. The slowest moving fraction moved at 0.1–1-mm per day and was believed to be the structural components. There were five major proteins, α - and β -tubulin and three proteins with apparent molecular

Figure 1 Diagrammatic representation of the NTFs. Note that the size of the proteins is dependent on the lengths of the C-terminal tails. The α -helical rod regions are shown as cylinders. The KSP phosphorylation sites in the tail regions are shown as yellow circles. The first two mutations linked to CMT disease in NFL are indicated.

weights of 68, 145, and 200 kDa. As actin, the component of the microfilaments, moved somewhat faster than these five proteins, the three unidentified proteins were identified as the subunits of the other structural element, the neurofilaments. Biochemical verification came when neurofilaments were purified and isolated and the contaminating astroglial filaments were removed. Each subunit was purified and the ability of the purified proteins to assemble *in vitro* was determined and assayed by examining the assembled filaments under the electron microscope. These *in vitro* assembly studies showed that the 68 kDa protein, later called NFL, was necessary and sufficient for IF formation. The 145 kDa (NFM) and 200 kDa (NFH) proteins coassembled with NFL and their long C-terminal tails appeared to form the links that can be observed between filaments in the electron microscope. The actual sequences of each of these proteins were determined initially by protein sequencing and later by complementary DNA (cDNA) cloning. They are shown schematically in **Figure 1**. Like all other IFs they contain a central α -helical rod domain flanked by nonhelical N-terminal head and C-terminal tail. The rod domain contains α -helical segments that are represented as cylinders. The rod domain of NFL can be divided into three separate segments (1A, 1B, and 2), whereas those of NFM and NFH are separated into two segments. The NF proteins have variable size C-terminal tails. The lengths of the C-terminal tails determine the ultimate sizes of the three proteins.

The tails of NFM and NFH contain multiple lysine-serine protein (KSP) repeats (shown as yellow circles), which are sites for phosphorylation as described below. As mentioned above, NFL is necessary for filament formation. Using various assays to study protein-protein interactions, it has been demonstrated that NFL can form homodimers and heterodimers with NFM and NFH. These results are consistent with the earlier observations from *in vitro* assembly studies that NFL can form a filament, whereas the other two proteins require NFL to assemble into filaments. Interestingly, transfection studies have shown that rat or mouse NFL needed either NFM or NFH to form a filamentous network *in vivo*, indicating that rodent neurofilaments are obligate heteropolymers. Human NFL can self-assemble in the transfected cells, but this assembly is not very efficient. The other neuronal IF

proteins, peripherin, and α -internexin are able to self-assemble into homopolymers *in vitro* and *in vivo*, although NFM appears to have an inhibitory effect on the ability of peripherin to assemble into a filamentous network.

Neurofilaments have been suggested to play a role in regulating axonal caliber and thereby influencing axonal conduction velocity. This role has been confirmed by studies of the Japanese *quiver* quail, which has a premature termination codon in its NFL gene and consequently no neurofilaments in its axons. Normal radial growth is severely inhibited in the large caliber fibers. When the NFL gene was deleted in NFL knockout mice, no visible IFs were observed and there was axonal hypotrophy. There was also a substantial decrease in NFM and NFH in the NFL knockout mice, presumably because they were unstable, because they could not polymerize into filaments. Curiously, in spite of this hypotrophy, the NFL-deficient mice developed normally and showed no obvious neurological problems. However, loss of function of NFL in humans causes a severe neuropathy. NFM $^{-/-}$ and NFH $^{-/-}$ mice have even less severe phenotypes. Loss of NFM also resulted in some reduction of the caliber of large axons and some axonal loss, whereas the absence of NFH in transgenic mice resulted in an even more modest reduction in axonal caliber. Overexpression of NFL and either NFH or NFM in transgenic mice resulted in an increase in the number of neurofilaments as well as axonal caliber, also consistent with the role of neurofilaments in regulating axonal calibers.

NFs are characterized by their phosphorylation, a posttranslational mechanism that is thought to regulate their functions. NFM and NFH are phosphorylated mainly in the KSP repeats located in their C-terminal tail domains. These phosphorylation sites are depicted in the tail domains seen in **Figure 1**. NFH has 44–51 KSP residues, whereas NFM has 5–14 of these residues, depending on species. Phosphorylation of NFs induces extension of their side arms from the filament backbone, apparently increasing the spacing between individual filaments and ultimately the axonal caliber. Phosphorylated NFs are found in axons, while the nonphosphorylated forms are found in neuronal cell bodies and dendrites. A number of different kinases have been shown to phosphorylate the KSP residues of NFM and NFH. Phosphorylation of the KSP

residues has been proposed to be important for the increase of the radial growth of axons by increasing the nearest neighbor distances between the neurofilaments, possibly through electrostatic repulsion between the neurofilament side arms. The evidence for this proposal came from electron microscopy studies that showed that dephosphorylated neurofilaments were more closely spaced together than phosphorylated neurofilaments. In the dysmyelinated *Trembler* mouse mutant, there is a decrease in neurofilament phosphorylation and smaller axonal diameter. When segments of *Trembler* sciatic nerves were grafted onto control nerves, the *Trembler* segments still maintained their smaller diameters and dephosphorylated neurofilaments, whereas adjacent regions showed normal diameters and neurofilament phosphorylation. These studies were considered as strong evidence that phosphorylation of neurofilaments (especially of NFH) is a determinant of axonal diameter. It, therefore, came as a surprise that the NFH knockout mice showed only a slight decrease in nearest neighbor spacing of neurofilaments and did not change the axon caliber, indicating that NFH phosphorylation may be less important for the determination of axonal caliber than was predicted. To test this particular property of NFH more rigorously, the NFH gene was replaced in transgenic mice with one deleted in the NFH tail. The results showed that the loss of the NFH tail and all of its phosphorylation sites did not affect the interfilament spacing of the neurofilaments. By contrast, the NFM tail and its state of phosphorylation may be more important for radial growth, even though it contains considerably fewer phosphorylation sites.

As described before, neurofilament proteins are synthesized in the cell body and have been found to move down the axon as part of the slow component of axonal transport with a velocity of $\sim 0.1\text{--}1\text{ mm d}^{-1}$. The initial hypothesis was that the entire axoplasm moved as a coherent block, but more recent work has shown that the entire axoplasm in its totality does not move. Neuronal IFs are now thought to move as monomeric and polymeric units. Studies using proteins tagged with green fluorescent protein and live-video microscopy have demonstrated that neuronal IFs undergo rapid, intermittent, and nonsynchronous transport in both directions, with predominance of the anterograde transport and long pauses in between movements along the axons. These studies indicate that slow transport is actually the result of fast motions interrupted by long pauses. This fast transport is likely to utilize one of the many motors that have been identified for fast transport. These motor proteins could also be responsible for some of the cross-links observed between IFs and microtubules. Other potential cross-linkers are members of the plakin family of proteins that were first identified in junctions in epithelial cells. More recent studies have shown that some plakins are also expressed in the nervous system. Plakins have distinct domains that include microtubule, microfilament, and IF-binding domains and could, therefore, be important in the formation of cross-links between these cytoskeletal elements. The phosphorylation of the side chains of the neurofilaments described above has also been considered to be important for the regulation of transport of neurofilaments through axons. Two studies have provided different conclusions regarding the role of NFH side arm

phosphorylation in neurofilament transport. In one study, all the potential phosphorylation sites of NFH were mutated either to preclude phosphorylation or mimic permanent phosphorylation of the NFH side arms. These mutants displayed altered rates of transport in a bulk transport assay. The mutant mimicking permanent phosphorylation spent a higher proportion of time pausing than one that could not be phosphorylated, indicating that NFH phosphorylation slows neurofilament transport. By contrast, in transgenic mice, where the endogenous NFH was replaced by a tailless NFH, there were no changes in the rate of bulk transport. These studies indicate that the mouse studies are not always consistent with the studies in cultured cells, in part, due to additional compensatory mechanisms that may exist in the mouse. In any case, some of these aspects of neurofilament transport will become clearer when the specific motors that move neurofilaments are identified.

α -Internexin

α -Internexin was first isolated from optic nerve and spinal cord and found to be particularly abundant in the developing nervous system. α -Internexin has an apparent molecular weight of 66 kDa and is, therefore, a little smaller than the NTFPs. Although it is present in both the CNS and PNS early in development, it is mainly CNS specific in the mature mammalian nervous system. Consistent with its expression early in development in the absence of other IFs, α -internexin has been shown to be able to self-assemble both *in vitro* and in transfected cells. α -Internexin is closely related to the NTFPs and is, therefore, also classified as a type IV IF protein. α -Internexin is the first neuronal IF expressed in neurons after they are committed to the neuronal lineage. The expression of α -internexin is high early in development and then decreases after the axon matures. In the PNS, the level of α -internexin decreases significantly in adulthood, although it persists especially in thinner unmyelinated axons. In the CNS, α -internexin expression is also lower after the axon matures. Of particular interest is the fact that α -internexin is the only neuronal IF expressed in some neurons, for example, the granule cell neurons in the cerebellum. The axons of these neurons are thinner in diameter than the ones that express the NTFPs suggesting that α -internexin is not important for maintaining axonal diameter. The early expression of α -internexin led to the suggestion that it might be important for axon outgrowth. Although this idea was supported by antisense inhibition experiments in cultured cells, the α -internexin knockout mice have no obvious phenotype. No compensatory changes in the levels of other neuronal IFs were observed and it appears that α -internexin is not necessary for axon outgrowth in these mice. Unfortunately, these knockout studies tell us little about other potential functions of this protein. Overexpression of α -internexin in transgenic mice results in the formation of cerebellar torpedoes. These torpedoes are swellings in Purkinje cell axons. The presence of these torpedoes results in the degeneration and ultimate death of the Purkinje cell. There is a dysfunction of the cell as determined behaviorally from the transgenic mice before the cells die.

Peripherin

Peripherin was first identified as an IF protein from neuroblastoma and its cDNA was cloned from a cell line that can be induced to grow neuronal processes by the addition of nerve growth factor, called PC12 cells. Peripherin has a molecular weight of 57 kDa and belongs to the type III IF proteins, which also consists of vimentin, the glial-specific GFAP, and the muscle-specific IF protein called desmin. Peripherin is, therefore, the only type III neuronal IF protein, because all the other neuronal IFs are in the type IV category. The significance of this difference is not known. Like all the other type III IFs, peripherin can self-assemble into a filamentous network. Peripherin can also coassemble with other neuronal IFs. Peripherin is predominantly found in the PNS (hence its name), but some CNS neurons also express peripherin. As described above, peripherin was identified as a gene that was increased in PC12 cells upon stimulation by nerve growth factor. Peripherin has also been shown to be upregulated following axonal injury. These studies suggested that peripherin may play a role in axon outgrowth and elongation. Peripherin depletion experiments with antisense technologies yielded conflicting results: initial studies showed that antisense oligonucleotides did not inhibit neurite outgrowth, whereas more recent studies using small interfering RNAs (siRNAs) showed that peripherin siRNA inhibits the initiation, extension, and maintenance of neurites in PC12 cells. The reason for this discrepancy is not clear. Peripherin knockout mice have normal caliber axons and show no axonal loss. As described in more detail below, some interesting observations have led to the possibility that misexpression of peripherin can lead to neurodegenerative disease.

Nestin

Nestin was first described as a marker of neuroepithelial stem cells. Subsequent cDNA cloning showed that a large IF protein encoded this marker. Nestin has the basic hallmarks of an IF protein with an α -helical rod, capable of forming coiled-coil dimers, a very short head domain and a very long tail domain. Nestin has little homology to the other mammalian IF proteins, but its genomic structure is similar to the NTFs and α -internexin. As a result, nestin is placed either as a separate type of IF (type VI), or as a type IV IF along with the NTFs and α -internexin. During early development, nestin is expressed in neuroepithelial cells and muscle progenitor cells. Transgenic mouse studies have indicated that different regulatory elements in the nestin gene are responsible for directing gene expression in developing muscle and neural precursor cells, respectively. Nestin is not able to self-polymerize, but requires vimentin to form a filamentous network. There have been no published reports of a nestin knockout mouse.

Neuronal Intermediate Filaments and Disease

Overexpression of neuronal IFs in transgenic mouse models results in the formation of mislocalized protein aggregates,

which affect neuronal function and survival. This has been shown in the case of human NFH, mouse NFL, peripherin, and rat α -internexin. The relationship between misexpression, disrupted transport, and mislocalization of neuronal IFs to neurodegeneration is also apparent from the appearance of axonal neurofilamentous accumulations in a number of neurodegenerative diseases. In particular, aggregation of IFs in motor neurons and alteration in their axonal transport has been reported in ALS. It appears likely that mutations in neurofilament proteins would also lead to neurodegeneration. When an assembly disrupting NFL mutant was produced in a transgenic mouse model, the mutant NFL caused massive degeneration of motor nerves. Several mutations have now been identified in neurofilament proteins that lead to neurodegenerative diseases. Deletions and insertions in the tail domain of NFH have been reported in 1–2% of patients with sporadic ALS; however, no familial cases of NFH mutations have been identified, making this connection a little bit more tenuous. There is a better-documented relationship between peripherin and ALS. Peripherin has been found in axonal spheroids in patients with ALS. Furthermore, overexpression of peripherin by four- to sevenfold in transgenic mice leads to late onset progressive motor neuron disease, which is accelerated in mice that lack NF. A number of mutations in peripherin have also been described in sporadic ALS cases. A number of mutations in the NFL gene have now been linked to Charcot–Marie–Tooth neuropathy type 2E. Two of these mutations (P8R and Q333P) are shown in [Figure 1](#). When these same mutations are introduced in an NFL cDNA and the mutant NFL constructs are expressed in cultured cells, defects in assembly and transport of NFL are observed. It appears, therefore, that these mutations in NFL might alter axonal transport, which, in turn, would cause neurodegeneration. This notion is consistent with the hypothesis that alterations in axonal transport (in which neuronal IFs could be directly or indirectly involved) play a role in the pathogenesis of other neurodegenerative diseases. A number of additional mutations have been described in both sporadic and familial CMT with varying degrees of severity depending on the site of the mutation. The mutations that have been described have all been in the head and the rod domain of NFL. A mouse model with one of these mutations (P22S) causes neuropathy in transgenic mice, which can be reversed by turning off the transgene. It is also of interest that in humans, a recessive *NEFL* mutation that appears to cause a simple loss of function results in a severe, early-onset axonal neuropathy.

Glossary

Neurotransmitter Message chemicals released from one neuron at the presynaptic nerve terminal.

Polymorphism A genetic variant in DNA sequence.

Synaptic cleft The gap between the pre- and postsynaptic neurons.

Neurotransmitters are chemical messengers by which neurons communicate with each other. Timely removal of neurotransmitters from the synaptic cleft is crucial for synaptic neurotransmission. If neurotransmitter molecules released during synaptic events were allowed to remain in the synaptic cleft, they would prevent new neuronal signaling mainly because the synapse would become refractory due to continued exposure of neurotransmitter. Removal of neurotransmitter from the synaptic cleft occurs by three mechanisms: diffusion, enzymatic degradation, and reuptake. High-affinity reuptake for the released neurotransmitters is mediated by transporter proteins localized at the membrane of nerve terminals and glial cells, and is the most common mechanism for the termination of synaptic events. This mechanism serves not only to clear the extracellular component of the synapses of neurotransmitter but also to recapture transmitter molecules for later reuse. In addition to their obvious and crucial role in neurotransmitter homeostasis, transporters are also important targets for therapeutic drugs as well as drugs of abuse and known neurotoxins.

Neurotransmitter transporters utilize the electrochemical energy derived from the movement of ions to drive the intracellular accumulation of neurotransmitter. In the early 1990s, several of these membrane proteins were cloned (the genetic sequence of DNA was identified) and two wide families have been identified. The first (SLC6 family), which includes the norepinephrine (NE), dopamine (DA), γ -aminobutyric acid (GABA), and serotonin (5HT) transporters, shares no significant sequence homology with the second (SLC1 family), which includes transporters for glutamate. After the cloning of these membrane proteins, there were several intriguing and exciting questions: What is the mechanism of transport? How does the protein structure define the functional properties of the transporter? What are the cellular signals and determinants that regulate transporter expression and function? Are there disease states related to neurotransmitter transporter dysfunction?

Mechanisms of Transport

Reuptake and Electrogenicity

Neurotransmitter transporters operate by coupling the transmembrane translocation of substrate to the movement of driving ions down pre-established electrochemical gradients (co-transport). Members of the SLC6 family include the DA

transporter (DAT), 5HT transporter (SERT), NE transporter (NET), and GABA transporter (e.g., GAT1) that are dependent on both extracellular sodium (Na^+) and chloride (Cl^-) to function, whereas the glutamate transporters (EAATs) depend on extracellular Na^+ and intracellular potassium (K^+). Both families of transporters use the Na^+ gradient generated by high extracellular Na^+ and low intracellular Na^+ to drive uptake of neurotransmitter into cells. The most widely held concept of how co-transporters function is founded on the alternating access model, in which the binding sites for substrates and ions are alternately exposed to extracellular or cytoplasmic environments via conformational changes in the transporter protein. The thermodynamic work of the transporter is accomplished by coupling the flux of substrate to the movement of co-transported ions down their electrochemical gradients. The exact stoichiometry of ions depends on the transporter and can even be modulated by regulatory proteins. The neurotransmitter transporter process is electrogenic, meaning that the transport process moves net charges across the plasma membrane due to the movement of ions accompanying the movement of the neurotransmitter. Indeed, in both heterologous cell lines expressing transporters and in native neurons in cell culture, electrical currents generated by transporters have been reported. In addition to the stoichiometric current due to movement of ions coupled to neurotransmitter transporters, electrical current that is independent of, or uncoupled from, neurotransmitter movement has been reported through transporters. Particularly notable are the relatively large Cl^- currents through the glutamate transporters, although uncoupled currents are also known for the monoamine transporters including DAT. These uncoupled currents through the transporters are large enough in magnitude to alter neuronal membrane potential and excitability.

Recent electrophysiological studies of both native and cloned neurotransmitter transporters revealed that they have brief and rare channel-like openings comparable to those generated by ligand-gated ion channels. Models for this exiting mode of the neurotransmitter transporters have been established, in which substrate and ions induce the carrier to transport in the alternating access mode (Figures 1(a) and 1(b)), and rarely switch to a channel-like mode (Figure 1(c)). The alternating access model assumes that the substrate permeation occurs through a state transition ($A \leftrightarrow B$) and results in the transport of a single neurotransmitter molecule (Figures 1(a) and 1(b)). The channel-like mode (Figure 1(c))

Figure 1 Model for neurotransmitter transporters function. S indicates a substrate molecule and the red circles depict a co-transported ion. The conformational switch between A and B is the classical alternating access model of co-transport. C represents the channel-like conformation that allows rapid bursts of ions and/or substrates to move across the membrane.

is a low-probability event that consists of hundreds of ions crossing the membrane (using the transporter aqueous pore) down their electrochemical gradients.

Reverse Transport

In addition to mediating the reuptake of neurotransmitter into nerve terminals, transporters can also cause nonvesicular release (efflux) of the neurotransmitter from the nerve terminal due to the transporter operating in reverse moving the substrate from the inside to the outside of the cell. This process can be induced by conditions that change the gradient of neurotransmitters and/or ions. For example, the abused psychostimulant amphetamine increases the concentration of dopamine on the inside of the cell as well as alters the gradient for Na^+ , resulting in a reverse transport of dopamine from the inside to the outside of the cell. Nonvesicular neurotransmitter release is thought to play a role under certain pathophysiological conditions. Ischemia during stroke impairs the normal Na^+ and K^+ gradients due to the inability of the Na^+/K^+ adenosine triphosphatase (ATPase) pump to function properly. The alteration of these ion gradients leads to reverse transport of glutamate through GluTs and subsequent toxicity from excess glutamate receptor activation. The direction of transport is also voltage dependent and there is evidence that physiological depolarization may induce some reverse transport in response to neuronal depolarization for both dopamine transporters and glutamate transporters.

Structure and Function

A major milestone for understanding the relationship between the structure and function of neurotransmitter transporters came in the form of the determination of the crystal structure for bacterial homologs for both the glutamate (SLC1) family and the monoamine (SLC6) family. Both structures generally confirmed earlier models of transmembrane domain topology based on hydrophathy predictions, site-directed mutagenesis, accessibility of individual residues to domain-specific antibodies, and accessibility of individual residues to chemical modification of engineered cysteine residues. Nonetheless, some details were surprising such as the broken conformation of helices surrounding the substrate-binding sites. The crystal structures have become

valuable tools both for the rational design and the interpretation of structural and function studies examining the interaction of substrates and drugs with the transporter, the conformational changes underlying transporter function, and the effects of altering specific amino acid structures on the transporters.

Regulation

It is not surprising that molecules regulating the spatial and temporal dimension of synaptic events are tightly regulated. Several reports have shown that many of the neurotransmitter transporters can be rapidly regulated by various signaling molecules. Regulators of neurotransmitter transporter activity include G-protein-coupled receptors such as the D_2 and mGluR5 receptors, kinases such as protein kinase C (PKC), phosphatidylinositol 3-kinase, tyrosine kinase, Ca^{2+} /calmodulin kinase, protein kinase B, neurotrophic factors, and hormones including insulin. In addition to uptake rates, some studies suggest that the regulation of neurotransmitter transport capacity might originate from a change in transporter cell-surface expression. In this context, it is important to point out that plasma membrane expression level of neurotransmitter transporters is finely controlled by transporter interacting proteins. For example, in addition to PKC and other signaling pathways, cell-surface expression and/or activity of GAT1, SERT, NET, and DAT are regulated by syntaxin 1A, a protein involved in synaptic vesicle fusion to the plasma membrane. Other regulators of DAT, NET, and SERT cell-surface expression include psychostimulants such as amphetamine and cocaine.

The general process of transporter trafficking, that involves endocytosis, intracellular sorting, and exocytosis of these membrane proteins, is acquiring great interest for neuroscientists. This is because researchers studying transporter cell-surface redistribution are envisioning the possibility of discovering new cellular targets for the cure of neurological disorders.

Relationships between Disease States and Neurotransmitter Transporters

The ability of the neurotransmitter transporters to regulate normal synaptic signaling implies that functional modification

of transporter activity might contribute to the etiology of multiple neurobiological diseases. Indeed, early studies have shown that the monoamine transporters NET, DAT, and SERT play an important role in regulating mood, learning, and motor activity, while GABA transporters have been implicated in neuronal excitability dysfunction such as epilepsy. While many years of innovative pharmacology resulted in the development of compounds that, by targeting neurotransmitter transporters, alleviate the symptoms of neurological diseases such as drug abuse and attention-deficit hyperactivity disorder (ADHD), new hopes for the cure of these conditions are coming from studying the gene organization and polymorphisms of these membrane proteins. Indeed, it has been shown that genetic variations in the human neurotransmitter transporters sequences known as 'polymorphisms' may alter transporter-expression level, activity, or regulation that ultimately may influence the levels of extracellular neurotransmitter.

Recently, genetic studies have associated specific polymorphisms in neurotransmitter transporters with human disease, and especially polymorphisms that lead to changes in the coding sequences have facilitated studies to determine the molecular mechanisms for these diseases. An example of a specific transporter genetic variant associated with human disease is the DAT variant A559V found in some children with ADHD. Molecular studies of this transporter suggest that anomalous reverse transport of dopamine may contribute to ADHD and that variation in the DAT gene may explain how psychostimulants are effective treatments for some children

with ADHD. As more genetic data becomes increasingly available, there will be ever-expanding opportunities to investigate how genetic variability in neurotransmitter transporters contributes to human disease and to design more rational treatment for these diseases.

Glossary

Apoptosis A form of cell death involving a series of programmed biochemical events, it is also called programmed cell death.

c-Jun-N-terminal kinase (JNK) Kinase enzyme, responsive to stress stimuli and phosphorylates several substrates.

Neurotrophin A member of a family of homologous growth factors that promote the survival and differentiation of neurons.

Nuclear factor kappa B (NF- κ B) A transcription factor.

Phosphatidyl-inositol 3 kinase (PI3K) Kinase that phosphorylates inositol lipids on the third position of the sugar.

PLC- γ An enzyme that cleaves phosphatidyl inositol (4,5) bisphosphate to release inositol-3-phosphate and diacyl glycerol (DAG).

Proneurotrophin Uncleaved form of neurotrophins.

p75NTR The 75-kDa neurotrophin receptor.

Receptor A cell surface protein specifically binds to particular substrate (e.g., ligand).

Trk The tyrosine kinase neurotrophin receptor.

The neurotrophins are a family of dimeric, secretory proteins, necessary for nervous system development and function. The members of the neurotrophin family include nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), and neurotrophin 4 (NT4), and each is essential for the survival of specific, but overlapping, populations of neurons during development. Given that nearly half of the neurons generated during development undergo programmed cell death, it is clear that neurotrophins have a major role in determining the ultimate population size for a given group of neurons. The neurotrophins not only promote survival, but also regulate cellular differentiation, axon guidance, synaptogenesis and plasticity, myelin formation, and neurite branching and elongation. Hence, this family of trophic factors has a wide spectrum of actions that are key for the proper sculpting of the mammalian nervous system. In addition to their role in development, this family of proteins also has important effects on maintenance of the nervous system, including processes such as learning and memory, neurogenesis, and response to injury. Like other secretory proteins, neurotrophins are generated from precursor proteins (proneurotrophins). However, these proneurotrophins are not simply transient intermediates in the biosynthesis of the mature protein, they can be secreted and are functionally active, promoting apoptotic cell death. This article focuses on the molecular signaling pathways activated by the neurotrophins and how these signals regulate neuronal survival and death.

The broad range of biological functions exerted by neurotrophins reflects the variety of signaling pathways that are influenced by activation of their receptors. The neurotrophins bind to two unrelated receptor types, a family of tyrosine kinase receptors, the Trks, and a member of tumor necrosis factor (TNF) family, the p75 neurotrophin receptor (p75NTR). Neurotrophin binding to the Trks promotes survival and differentiation while activation of p75NTR can also enhance cell viability or, paradoxically, induce apoptosis. Although activation of the Trks or p75NTR can initiate discrete signal transduction pathways, the two receptor types are frequently

coexpressed on a given cell and can function in a complex. In addition to the Trk/p75NTR complex, the p75NTR can interact with several other transmembrane proteins, forming various complexes. Thus, it is the manifold interactions between these receptors and the cross-talk between their signaling pathways that ultimately determines the fate of the cell. These receptor interactions, the signaling pathways activated, and their functional implications are discussed.

Neurotrophin Signaling through Trk Receptors

The most well-studied actions of neurotrophins are mediated through activation of a family of tyrosine kinase receptors, the Trks. There are three members of the Trk family, TrkA, TrkB, and TrkC. Each receptor binds to specific members of the neurotrophin family preferentially with NGF having high affinity for TrkA, BDNF, and NT4/5 for TrkB, and NT3 for TrkC. In addition, NT3 can also activate other Trk receptors with less specificity. Binding of a neurotrophin to a Trk receptor triggers receptor dimerization and activation of intrinsic tyrosine kinase activity. The intracellular domains (ICDs) of the Trk receptors contain 10 evolutionarily conserved tyrosine residues, three of which are in an autophosphorylation loop of the tyrosine kinase domain. Similar to other receptor tyrosine kinases, phosphorylation of these tyrosine residues results in increased Trk tyrosine kinase activity. Phospho-tyrosine residues in the ICD serve as docking sites for proteins containing Shc-homology 2 (SH2) or phospho-tyrosine-binding domains, including the enzyme phospholipase C- γ (PLC- γ) and the adaptor proteins Shc, fibroblast growth factor receptor substrate 2 (Frs-2), rAPS, and SH2-B. The major pathways activated by the Trk receptors are the Ras/MAP kinase pathway, the PI3 kinase/Akt pathway, and the PLC- γ pathway and their downstream effectors (MAP kinase, mitogen-activated protein kinase).

Phosphorylation of TrkA at Y785 and similar sites on TrkB and TrkC recruits the cytoplasmic enzyme PLC- γ , which

Figure 1 Neurotrophin signaling through Trk receptors. Neurotrophin binding to Trk receptors phosphorylates tyrosine residues in the intracellular domain and increases tyrosine kinase activity. Three major pathways get activated in response, the Ras/MAP kinase pathway, the PI3 kinase/Akt pathway, and the PLC- γ pathway, and these regulate cell survival, differentiation, and long-term potentiation.

associates with Trk receptors through its SH2 domain and is then phosphorylated by the receptor. Active PLC- γ cleaves phosphatidylinositol 4,5-bisphosphate to release the second messengers inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG) (Figure 1). DAG activates specific isoforms of protein kinase C (PKC), while IP3 triggers the release of Ca^{2+} from intracellular stores, which activates a variety of pathways, including calmodulin kinases and Ca^{2+} -regulated isoforms of PKC. The maintenance of calcium homeostasis has been well documented as key for regulating neuronal survival. Indeed, a role for PKC in the prosurvival effects of the neurotrophins has been suggested; however, this pathway also has been implicated in regulating spatial learning and memory. Analysis of transgenic, knock-in mice lacking the docking site for PLC- γ on the TrkB receptor has not revealed any defects in neuronal survival, but the animals do display deficiencies in hippocampal long-term potentiation, which is a model for spatial memory. The activation of PLC- γ also modulates the activity of TRP channels, a family of cation channels involved in thermal and mechanical sensation.

Another signaling cascade activated by the Trk receptor is the Ras–MAP kinase pathway. Stimulation of this pathway occurs through the binding of several different adaptors to the Trk receptors. The transient activation of Ras is mediated by the adaptor protein Shc, which is recruited to a phosphorylated tyrosine residue (Y490 on TrkA), leading to docking of the adaptor proteins Gab1, Gab2, and Grb2. Grb2 associates with the guanine-nucleotide-exchange factor Son of sevenless, which facilitates the activation of Ras, a guanosine triphosphate (GTP)-binding protein that activates several pathways.

Additional scaffold proteins, including SH2-B, adaptor protein with pleckstrin homology and Src homology-2 domains (APS), and insulin receptor substrate-1 (IRS1), also provide links to Ras. The activated, GTP-bound form of Ras recruits the serine/threonine kinase Raf to the plasma membrane, promoting its activation. Raf then phosphorylates MEK1 and/or MEK2 and these kinases phosphorylate the MAP kinases Erk1 and Erk2 (Figure 1). Ras also promotes the activation of the MAP kinase Erk5, through a cascade involving the upstream kinase MEK5.

The ability of neurotrophins to promote differentiation appears, in part, to depend on prolonged Erk1/2 activation, as opposed to the transient activation of the kinases induced by other growth factors such as EGF. The sustained activation requires a different adaptor protein, Frs-2. Frs-2, activated by binding to phosphorylated Y490 on Trk receptors, provides a binding site for the adaptor proteins Grb2 and Crk. Crk binds to the guanine-nucleotide-exchange factor C3G, which then stimulates the small GTP-binding protein Rap1. Alternatively, Crk can also associate with Trk receptors through binding to the transmembrane protein ankyrin repeat-rich membrane-spanning adaptor (ARMS). Upon neurotrophin binding to the Trk receptor, ARMS is phosphorylated, which creates a binding site for Crk, leading to Rap1 activation through C3G. The kinase B-Raf is then activated by Rap1, which results in sustained Erk1/2 activation (Figure 1).

The Erks, activated by neurotrophins/Trk receptors, translocate into the nucleus and regulate gene expression directly by phosphorylating transcription factors such as cAMP response element-binding (CREB), Egr-1, and Elk-1 or indirectly through the phosphorylation of a variety of substrates including the

ribosomal S6 kinase (RSK), which can then phosphorylate and inactivate the proapoptotic protein Bad. RSK also phosphorylates the transcription factor CREB, resulting in its activation and the subsequent upregulation of downstream genes to regulate cell survival and differentiation of neurons.

Another Trk-mediated signal that promotes neuronal survival and neuroprotection is the activation of the lipid kinase, phosphatidylinositol 3 kinase (PI3-kinase). Active Ras can lead to PI3-kinase stimulation; however, this kinase is also activated independent of Ras through Shc-Grb2 or through IRS1. Neurotrophin binding to Trks recruits Gab1/2 to phosphorylated Grb2, resulting in binding, phosphorylation, and activation of PI3-kinase. Trk receptor activation also leads to phosphorylation of IRS1, which permits activation of PI3-kinase. PI3-kinase produces P3-phosphorylated phosphatidylinositides and these serve to indirectly activate the serine/threonine kinase Akt. Akt phosphorylates and regulates several signaling proteins that are critical factors controlling cell survival. It inhibits the proapoptotic proteins BAD, forkhead transcription factors, GSK3 β and caspase 9, and induces the activation of the prosurvival transcription factor nuclear factor kappa B (NF- κ B). Several studies have demonstrated a requirement for the PI3-kinase-Akt pathway in neurotrophin-mediated survival; however, this pathway also promotes protein translation, neurite branching, and neuronal differentiation (Figure 1).

Adding to the complexity of Trk signaling is the existence of several splice variants of all of these receptors. Among these isoforms, both TrkB and TrkC exist as truncated receptors with short cytoplasmic motifs lacking the tyrosine kinase domain. Although there is evidence that loss of the kinase domain can function to abrogate Trk signaling, such as activation of PLC- γ , by competitively binding the available neurotrophin or forming inactive complexes with full-length receptors, there is also evidence that these truncated Trks may function to display bound neurotrophin to adjacent cells. In addition, recent findings suggest that the truncated T1 isoforms of TrkB and TrkC receptors can mediate signaling on their own, including the release of calcium stores and the regulation of the small GTPase Rac1, respectively. A second type of splice variant observed for all of the Trks is a form of the receptor lacking a small portion of the extracellular domain in the juxtamembrane region. Expression of these isoforms more stringently restricts the responsiveness of a given Trk for its cognate neurotrophin. For example, the TrkA isoform with the insert is activated by NT3 in addition to NGF. This may be one mechanism to insure the elimination of neurons making connections to an inappropriate target tissue.

One important aspect of neurotrophin signaling that needs to be considered is the spatial limitations of a neuron. Pioneering work by Rita Levi-Montalcini demonstrated that neuronal survival is critically dependent on their targets, which are often far removed from the cell soma. Typically, it is the axonal tip that encounters the neurotrophins, while the regulation of survival involves transcriptional activity; hence, the signaling must be retrogradely transported some distance back to the neuron soma. It has long been known that neurotrophins are retrogradely transported; however, it was only recently demonstrated that it is essential that the factor be transported with the active receptor, although this requirement has been contended by Campenot and colleagues. TrkA and NGF are not transported alone, rather, NGF-TrkA signaling leads to endocytosis of a

ligand-receptor complex and formation of signaling endosomes (signalosomes) containing numerous signaling components. These signalosomes are then transported retrogradely to the neuron cell body, where gene expression is regulated.

The mechanisms regulating the endocytosis and trafficking of the Trk receptors is a topic of intense investigation. The binding of neurotrophin to a Trk receptor stimulates internalization through a clathrin-mediated process; however, endocytosis has also been shown to occur through a novel protein, Pincher. The internalization and subsequent trafficking of Trk receptors is regulated by ubiquitination by E3 ubiquitin ligases. For example, the E3 ligase Nedd4-2 is phosphorylated upon TrkA activation, which leads to TrkA ubiquitination and down regulation. There remain many unknown mechanistic details of Trk internalization and the subsequent vesicular sorting.

Neurotrophin Signaling through p75 Neurotrophin Receptor

The p75NTR was the first neurotrophin receptor discovered, identified as a low-affinity receptor for NGF and subsequently shown to bind all the neurotrophins with equal affinity. This receptor plays an important role in regulating cell death during neuronal development and in response to nervous system injury. In addition, p75NTR signals modulate myelination, synaptic plasticity, neurite growth, cell-cycle regulation, and the invasiveness of tumor cells (Figure 2).

The p75NTR is the founding member of the tumor necrosis receptor family, which is comprised of single-pass transmembrane proteins containing cysteine-rich repeats in their extracellular domain and having a region of weak homology in their ICD referred to as a Death Domain, which mediates protein-protein interaction. In neurons, p75NTRs have been shown to exist as dimers, linked through a highly conserved cysteine²⁵⁷ in the transmembrane domain of the receptor that forms a disulfide bond. Binding of dimeric neurotrophins to preexisting p75NTR dimers leads to conformational rearrangement of the receptor, thereby initiating downstream signaling.

p75NTR contributes to a plethora of signaling complexes. It associates with several coreceptors, including the Trk receptors, Sortilin, Nogo-receptor, Lingo-1 and Ephrin A, and it mediates the response to multiple ligands, including NGF, BDNF, NT3, NT4, proneurotrophins, myelin-associated glycoprotein (MAG), Nogo, and oligodendrocyte myelin glycoprotein (OMgp) (Figure 2). Given this diversity of receptor complexes and ligands, it is not surprising that p75NTR can activate multiple signaling pathways with important physiological consequences. Nevertheless, the molecular mechanisms by which the receptor mediates the many downstream responses remain poorly understood. In an attempt to understand how the receptor transduces its signals, a number of proteins have been identified that can bind to its ICD, including neurotrophin receptor-interacting factor (NRIF), TNF α receptor-associated factor 6 (TRAF6), Rho-GDI, p75NTR-associated death executor, the neurotrophin receptor interacting melanoma antigen gene (MAGE) family members neurotrophin receptor-interacting MAGE homolog (NRAGE) and Necdin, Schwann cell factor 1 (SC1), receptor-interacting factor 2 (RIP2), brain-expressed-X-linked 1 (Bex1), and the actin bundling protein Fascin (Figure 2).

Figure 2 Neurotrophin signaling through the p75 neurotrophin receptor. Binding of either mature-neurotrophins, proneurotrophins, or nonneurotrophin ligands to the p75NTR extracellular domain leads to the recruitment of multiple adaptor proteins to the intracellular domain. These intracellular interactors initiate a wide range of signaling pathways, depending on cellular context and existence of coreceptors. Signaling pathways activated by the p75NTR regulate cell survival, cell death, myelination, cytoskeletal changes, cell cycle, long-term depression, and cell migration.

The first-recognized function of neurotrophin binding to the p75NTR was to facilitate the prosurvival signals generated by the TrkA receptor. When coexpressed, TrkA and p75NTR form a high-affinity-binding complex that increases the specificity of neurotrophin binding to TrkA and enhances tyrosine kinase signaling and the subsequent trophic effects. However, in specific contexts, p75NTR can also promote survival independent of the Trks. One of the best-characterized antiapoptotic signals generated by receptors in TNF receptor superfamily is the activation of the transcription factor, NF- κ B. This transcription factor can also be activated by p75NTR and was shown to mediate a survival signal in neurons and glia. This signal involves the recruitment of RIP2 and TRAF6 to the ICD of the receptor after neurotrophin binding leading to activation of NF- κ B (Figure 2).

The most surprising cellular response to p75NTR activation is the induction of programmed cell death. Although neurotrophins were discovered and best characterized for their ability to promote neuronal survival, it is now well established that neurotrophin binding to p75NTR in the absence of Trk signaling can induce an apoptotic response in specific cellular contexts. Furthermore, the proforms of the neurotrophins are selective p75NTR ligands and have been shown to induce apoptosis in many cell types. Like most-secreted peptides, the neurotrophins are initially translated containing an amino terminal domain that is proteolytically removed to form the mature, active protein. However, Hempstead and colleagues found that proNGF and proBDNF bind selectively to p75NTR, but not to TrkA or TrkB, and can potently induce apoptosis.

The proneurotrophins activate p75NTR through binding to a receptor complex that includes p75NTR and the VPS10P-domain receptor, Sortilin. The prodomain of proNGF or proBDNF binds to Sortilin, while the mature portion of the neurotrophin binds to the p75NTR. Although Sortilin is required for the proNGF or proBDNF binding, it is not clear how it may contribute to the apoptotic signal. The mechanisms regulating secretion of the proneurotrophins are not known; however, proNGF was detected in the cerebral spinal fluid of rats after lesion of the cortico-spinal tract and antibodies to the prodomain attenuated the resulting death of the cortical neurons. These findings suggest that proNGF may be released in response to certain neuronal injuries.

Numerous insults to the nervous system upregulate the expression of p75NTR and, in several instances, the receptor has been shown to mediate the accompanying apoptosis; for example, in hippocampal neurons after the induction of seizures, cortico-spinal neurons after axotomy and in oligodendrocytes after spinal cord injury. In addition, increased p75NTR expression has been observed in a wide variety of neuropathologies, such as focal ischemia, axotomy, stroke, Alzheimer's disease, and motor neuron disease, leading to speculation that p75NTR may be involved in these neuropathologies. P75NTR is also involved in regulating the naturally occurring cell death of specific neuronal populations during the development of the mammalian nervous system. Apoptosis mediated by p75NTR has been demonstrated to occur *in vivo* in the developing rodent spinal cord, retina, forebrain, and sympathetic ganglia.

Given the critical role p75NTR plays in regulating cellular viability during development and after injury, the molecular mechanisms that mediate the apoptotic signal are under intensive investigation. Like many members of the TNF receptor superfamily, p75NTR activates the stress kinase, c-Jun N-terminal kinase (JNK) and this signal is necessary for the receptor to induce apoptosis. Several p75NTR-interacting proteins have been linked to JNK activation, such as NRAGE, TRAF6, and NRIF. Genetic deletion of NRAGE, NRIF, or TRAF6 prevented the receptor from activating the kinase, suggesting that all three interactors contribute to this pathway, although the mechanistic details remain to be determined (Figure 3).

Cell death induced by JNK activation has been shown to occur through both transcription-dependent and independent mechanisms; for example, JNK activates members of the AP-1 family of transcription factors, leading to upregulation of proapoptotic genes such as Bim, Bak, and Fas ligand, and it also promotes apoptosis through phosphorylation of cell death factors such as p53, BAD, and Bim. Similarly, p75NTR-mediated cell death was demonstrated to involve JNK phosphorylation of Bim, Bad, and p53. However, protein synthesis inhibitors can block p75NTR-dependent apoptosis, suggesting that transcription may have a role (Figure 3).

A role for transcription in p75NTR-mediated apoptosis was also indicated by the fact that NRIF, a p75NTR-interacting protein that also can bind DNA, can be found in the nucleus following receptor activation by proapoptotic ligands. Nuclear localization of NRIF was found to be essential for p75NTR-mediated cell death, because a point mutant of NRIF, unable

to translocate to the nucleus, failed to reconstitute receptor-mediated apoptosis in *nrf1*^{-/-} neurons. The mechanism by which activation of the receptor facilitates NRIF nuclear translocation is reminiscent of signaling activated by the Notch receptor. Upon binding an apoptotic ligand, the receptor undergoes proteolytic cleavage first by TNF α -convertase enzyme (TACE) and then by the γ -secretase complex, thereby releasing the ICD. The liberated ICD allows for nuclear translocation of NRIF and subsequent apoptosis (Figure 3). The genes regulated by NRIF have yet to be identified. In addition, the mechanism by which p75NTR cleavage is regulated and how it relates to JNK activation remains unknown.

Proteolysis of the receptor by γ -secretase also plays a role in the regulation of neurite outgrowth by p75NTR. The myelin proteins Nogo, MAG, or OMgp bind to the Nogo receptor (NgR), a glycosylphosphatidylinositol-linked protein with no ICD, and this promotes the association of the NgR with p75NTR and another transmembrane protein termed Lingo-1. The formation of this complex recruits the guanine-nucleotide-exchange protein Kalirin9 and the Rho inhibitor Rho-GDI, resulting in activation of the small GTP-binding protein RhoA. This signaling pathway requires cleavage of the p75NTR, although how receptor processing facilitates the cascade is not clear. The activation of Rho causes reorganization of the actin-cytoskeleton, leading to growth cone collapse and the inhibition of axonal growth.

The ability of p75NTR to regulate the actin-cytoskeleton also plays a role in the migration and invasiveness of some tumor cells. Recent findings revealed that the most invasive cells in human gliomas express high levels of the p75NTR and

Figure 3 Proapoptotic signaling by the p75 neurotrophin receptor. Activation of the p75NTR by proapoptotic ligands activates the JNK pathway to induce apoptotic cell death. In addition, p75NTR undergoes regulated proteolytic cleavage by TACE and γ -secretase to release its intracellular domain, which is required for NRIF nuclear translocation and receptor-mediated cell death.

that expression of this receptor was sufficient to convert non-invasive gliomas to highly invasive tumors when xenografted into mice. The expression of the receptor in glioma cells was sufficient to induce RhoA activation and the formation of actin filaments. Similarly, the receptor is highly expressed in aggressive, invasive, malignant melanomas, and neurotrophin binding to p75NTR on these cells *in vitro* increased their invasiveness and promoted their survival. Neurotrophin-mediated migration of melanoma cells *in vitro* involved receptor binding to the actin bundling protein Fascin (Figure 2). Together, these findings suggest that p75NTR might be a target for developing therapeutic strategies for these deadly cancers.

In contrast to its action in melanoma and glioma cells, in prostate cells the p75NTR has been suggested to function as a tumor suppressor, promoting cell death and preventing cell proliferation. Interestingly, several of the receptor-interacting proteins have been shown to regulate the cell cycle, including NRIF, SC1, and Bex1. Indeed, SC1 can bind directly to the promoter for cyclin E and suppress its transcription. Given the widespread expression of p75NTR during embryonic development, particularly on many progenitor cells, it is provocative to consider the possibility that this receptor may control the population size of progenitors not only through apoptotic signaling, but also by modulating their rate of proliferation.

In addition to the aforementioned pathways, neurotrophin binding to the p75NTR has been shown to initiate a lipid-based signal. The receptor stimulates acid sphingomyelinase, which cleaves sphingomyelin to produce the second messenger ceramide. An increase in cellular ceramide has been linked to the promotion of cell death as well as survival by the p75NTR. In addition, this lipid can modulate a wide variety of signaling pathways, such as ERK, PI3 kinase, JNK, and NF- κ B.

Cross-Talk between p75NTR and Trk Receptor Signaling

In many neurons, Trk receptors are coexpressed with the p75NTR; thus, any neurotrophin binding to a Trk receptor will also activate the p75NTR. As these receptors can initiate divergent signaling pathways with opposing consequences, there must be mechanisms in place that ultimately allow the transduction of a consistent biological response. When both receptors are present, they interact to form a selective, high-affinity Trk-p75NTR complex. The interaction of p75NTR and Trk increases binding affinity for mature neurotrophins and enhances Trk tyrosine kinase activity, resulting in more robust

activation of downstream survival signals. This enhanced signaling is particularly important given the limiting amounts of neurotrophins available at target tissues. However, to promote survival, Trk must also prevent p75NTR from initiating its apoptotic cascade. Although the mechanisms by which this suppression occurs have yet to be fully elucidated, it is known that activation of the PI3-kinase–Akt pathway can inhibit JNK activation. For example, Akt can bind the scaffolding protein JNK-interacting protein 1 and displace members of the JNK cascade. In addition, both receptors can associate with TRAF6 (TrkA interacts via the adaptor p62), and this E3 ligase promotes the activation of NF- κ B, leading to upregulation of prosurvival genes. Similarly, ARMS bridges p75NTR and TrkA and leads to prolonged ERK activation. How ARMS affects p75 signaling, though, is not known. Clearly, there is much yet to learn about the complex relationship between the signaling pathways initiated by these two types of neurotrophin receptor.

Glossary

Membrane protein A membrane-associated protein, in this context an integral membrane protein spanning the membrane.

NAD(H) Oxidized (NAD^+) and reduced (NADH) nicotinamide adenine dinucleotide, a common cofactor in cell metabolism, especially catabolism.

NADP(H) Oxidized (NADP^+) and reduced (NADPH) nicotinamide adenine dinucleotide phosphate, a common cofactor in cell metabolism, especially anabolism.

Proton pump A group of membrane proteins catalyzing a translocation of protons across the membrane, driven by either redox energy, an ion gradient, or adenosine triphosphate.

Transhydrogenases A group of enzymes composed of two subgroups: a soluble flavine-containing type and a membrane-bound and proton-translocating type. Both catalyze the transfer of a hydride ion between NAD(H) and NADP(H).

Introduction

Proton-pumping nicotinamide nucleotide transhydrogenase (TH; E.C. 1.6.1.2) is an integral membrane protein found in most species except some yeasts, plants, and certain bacteria. It is located in the inner membrane of mitochondria and in the plasma membrane of bacteria. The enzyme catalyzes the reversible reduction of nicotinamide adenine dinucleotide phosphate (NADP^+) by a hydride ion, donated by NADH (the reduced form of nicotinamide adenine dinucleotide), which is linked to proton translocation across the membrane according to the reaction

In the absence of an electrochemical proton gradient (Δp), the reaction from left to right (the forward reaction) is approximately fivefold slower than the reverse reaction. Under these nonphysiological conditions, the overall reaction proceeds to an equilibrium with an equilibrium constant of close to 1. In the presence of a Δp , that is, under more physiological conditions, the forward reaction is increased 5- to 10-fold and the apparent equilibrium constant is increased to ~ 500 , with one proton translocated per NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate) formed. The net effect of the TH reaction is therefore probably to provide NADPH at the expense of NADH and Δp . Thus, this suggests important roles of TH in mitochondrial/cellular redox regulation including biosynthesis, detoxification (via the glutathione/thioredoxin systems), and apoptosis. TH is globally expressed in eukaryotes, that is, human, mouse, and *Caenorhabditis elegans*.

Proton-translocating THs from eukaryotes are homodimeric proteins with a relatively large hydrophilic domain composed of the NAD(H)-binding domain I (dI) and the NADP(H)-binding domain III (dIII); part of dI is homologous to alanine dehydrogenase (Figure 1). The hydrophobic part of the enzyme containing the proton channel, denoted domain II (dII), is composed of a variable number of transmembrane helices depending on species. The *Escherichia coli* TH is composed

of an α -subunit and a β -subunit, the former subunit containing dI and helices 1–4 of dII and the latter subunit containing dIII and helices 6–14 of dII. Intact *E. coli* TH has the composition $\alpha_2\beta_2$, that is, it is a tetramer in which $\alpha + \beta$ corresponds to the mitochondrial single polypeptide. dI and dIII can be expressed separately and purified in an active state and, when combined, show catalytic activity. In order to elucidate the coupling mechanism of TH, the enzyme mainly from bovine, human, and *E. coli* has been extensively studied in the purified forms, in cytosolic (plasma membrane) vesicles, as well as reconstituted in liposomal membranes. dI and dIII from bovine, human, and *Rhodospirillum rubrum*, as well as a complex between dI and dIII, have been structurally determined using X-ray crystallography and nuclear magnetic resonance (NMR).

Structure-Function of the Substrate-Binding Domains

Recent advances in structural resolution of the hydrophilic dI and dIII by X-ray crystallography and NMR spectroscopy have dramatically increased our knowledge about the structure-function relationships of these domains and their interactions. Thus, the crystal structure of the NAD^+ form of dI from *R. rubrum* solved by Jackson and co-workers, and in the NADH form from the same source later by Hatefi and co-workers, shows that it involves a dimer of a 40-kDa subunit, denoted as A and B. Each subunit comprises two subdomains, dI.1 and dI.2, both of which have a Rossmann nucleotide-binding fold composed of a sheet of parallel β -strands flanked by α -helices. The two domains are arranged on the sides of a deep cleft. However, in the crystal structure of the dimer only dI.2(A) contains bound NAD^+ positioned so that its nicotinamide moiety is exposed in the cleft. By contrast, dI.2(B) site contains disordered NAD^+ or no ligand. The arrangement of the monomers in the dimer is such that the nucleotide-binding sites in dI.2(A) and dI.2(B) are pointing away from each other. The potential nucleotide-binding sites in dI.1 (A) and dI.1(B) have no known ligands. It is obvious that in the dI dimer, dI.2(A)

Figure 1 Structural organization of proton pumping THs.

and dI.2(B) must have different conformations, because only dI.2(A) contains well-ordered NAD^+ . In a dimeric structure of dI with bound NADH, other minor but significant structural changes are observed. The structure of the corresponding dI from *E. coli* TH, recently solved by Krengel and co-workers, was nearly identical to that of the *R. rubrum* enzyme.

Human and bovine dIII have been structurally resolved by Jackson and co-workers and Hatefi and co-workers, respectively, using X-ray crystallography. These are structurally close to identical. The structures involve an alternating α/β -structure with a central β -sheet core, and a Rossmann fold in which NADP^+ is tightly bound at the C-terminal end of the β -sheet. The molecular mass of dIII is 20 kDa, it is a monomer, and it is isolated with predominantly tightly bound NADP^+ ; the K_d of the NADP(H) bound is in the nM– μM range. A striking difference, however, as compared with other NAD(P) -binding enzymes is that the NADP^+ bound to dIII is turned approximately 180° , that is, the nicotinamide ring is close to α -helix 3 in *E. coli* dIII (corresponding to α -helix B in *R. rubrum* dIII) (Figure 2). A number of hydrogen bonds stabilize NADP(H) in its binding site, involving, for example, Asp392, Lys424, Arg425, and Ser426. Loops D and E may indeed contribute to the binding and have been proposed to be involved in the Δp -dependent release of NADPH . Interactions between dI and dIII and their regulation by NADP(H) / NAD(H) have been investigated thoroughly by Karlsson and co-workers using NMR spectroscopy.

A crystal structure of a heterotrimer dI_2 –dIII complex from *R. rubrum* showed that the dI and dIII structures are essentially identical to those determined separately. However, the dI_2 –dIII

Figure 2 The NADP(H) -binding region of dIII. Amino acid residues and loops indicated are directly or indirectly essential in binding NADP(H) .

structure revealed that dIII interacts with the dI_2 (B), that is, the NAD(H) -binding site that contains disordered NAD^+ rather than well-ordered NAD^+ . This may be interpreted as indicating that when dIII (with bound NADP^+) is interacting with dI_2 , it binds the dI_2 (B) that has a disorganized NAD^+ , not the dI_2 (A) that has a well-ordered NAD^+ . However, a complicating fact is that, even though an NAD(H) molecule could be modeled in the dI_2 (B) site, the two nicotinamide rings are still separated by some 4–6 Å, making direct hydride transfer difficult. A possible mechanistic solution to this problem is that the nicotinamide ring of the modeled NAD(H) is

changed from an *anti* to a *syn* conformation, leading to a more open exposure of the nicotinamide ring in the cleft and a direct interaction with the nicotinamide ring of NADP⁺. Indeed, this rotation may be the very reason why NAD⁺ is more mobile in dI.2(B). An additional factor influencing the interaction between dI and dIII, and thus hydride transfer, is the amino acids that make up the interface between the domains. One of these, Gln132 in dI, appears to be essential for activity because it works as a tether during the catalytic cycle, holding both NAD(H) and NADP(H) together in the right conformation through H-bonds.

Mechanism of Hydride Transfer

Transfer of the hydride ion between the 4A-hydrogen (*pro-R*) of NADH and the 4B (*pro-S*)-hydrogen of NADP⁺, while the two substrates are bound to dI and dIII, respectively, occurs directly without any known intermediate and without exchange with bulk protons. Even though NAD⁺/NADH are rapidly exchanging with the NAD(H)-binding site in dI throughout the reaction cycle, NADH especially shows different affinities in the open (ordered and high affinity) and closed (disordered and low affinity) states. These affinity changes, and the associated *anti/syn* transitions of NAD(H), are apparently induced by subtle conformational changes in the dI dimer. However, several pieces of evidence together indicate that regulation of hydride transfer by, for example, an electrochemical proton gradient, Δp , occurs mainly at the level of dIII, rather than dI.

Essential information in this context was derived from the fact that separately expressed and purified dIII contains tightly bound NADP(H) which, due to a limiting release of the product NADP(H), catalyzes approximately two orders of magnitude slower reverse and forward reactions in the presence of purified dI than the wild-type enzyme. Isolated dIII also catalyzes a very fast so-called cyclic reaction, that is, reduction of 3-acetyl-pyridine-NAD⁺ (an NAD⁺ analog) by NADH, mediated by the bound NADP(H). This reaction involves reduction of bound NADP⁺ by NADH, release of the NAD⁺ formed, binding of 3-acetyl-pyridine-NAD⁺, reduction of 3-acetyl-pyridine-NAD⁺ by the bound NADPH, and release of 3-acetyl-pyridine-NADH. Indeed, it was reasonable to assume that the properties of the isolated dIII reflected an intermediate, the occluded state, in the reaction cycle of the intact TH. In reaction [1], this is interpreted to indicate that the activity of the forward reaction is limited by NADPH release, a limitation that is alleviated by Δp , allowing the enzyme to be catalytically fully active.

A general reaction scheme for forward reaction catalyzed by the *E. coli* TH may be outlined as follows (Figure 3). Starting with the resting state (state A), NADP⁺ binds to dIII in the β -subunit generating state B, in which the proton channel and the protonatable group X2 become accessible to the periplasmic space; in state C, the enzyme is protonated at X2, and the β -subunit subsequently changes conformation to state D. In state D, the proton moves from X2 to X1 concomitant with hydride transfer from NADH to NADP⁺, generating state E. States D and E correspond to the occluded state. Following a conformational change in dIII, an opening of dIII, and a less

Figure 3 Reaction cycle of the forward TH reaction. X1 and X2 denote two protonatable residues in dII, possibly His91 and Asn222, respectively. X3 is a protonatable group in dI unrelated to the proton channel.

tight NAD(H) (state F), the proton dissociates on the cytosolic side generating state G. After dissociation of NADPH, the enzyme returns to the resting state A. During the entire cycle NAD(H) can freely bind to and dissociate from dI. X3 indicates a group on dI that may be regulated by the cytosolic pH.
